viscera and fibers from specific areas of the skin converge on the same projection neurons in the dorsal horn. The brain has no way of knowing the actual site of the noxious stimulus and mistakenly associates a signal from a visceral organ with an area of skin. (Adapted, with permission, from Fields 1987)

local interneurons and supraspinal projection neurons. Many of these neurons receive input from A β afferent fibers that respond to innocuous cutaneous stimuli, such as the deflection of hairs and light pressure. Lamina V contains neurons that respond to a wide variety of noxious stimuli and project to the brain stem and thalamus. These neurons receive direct inputs from A β and A δ fibers and, because their dendrites extend into lamina II, are also innervated by C fiber nociceptors (Figure 24–3B).

Neurons in lamina V also receive input from nociceptors in visceral tissues. The convergence of somatic and visceral nociceptive inputs onto individual lamina V neurons provides one explanation for a phenomenon called "referred pain," a condition in which pain from injury to a visceral tissue is perceived as originating from a region of the body surface. Patients with myocardial infarction, for example, frequently report pain from the left arm as well as the chest (Figure 24–4).

This phenomenon occurs because a single lamina V neuron receives sensory input from both regions, and thus a signal from this neuron does not inform higher brain centers about the source of the input. As a consequence, the brain often incorrectly attributes the pain to the skin, possibly because cutaneous inputs predominate. Another anatomical explanation for instances of referred pain is that the axons of nociceptive sensory neurons branch in the periphery, innervating both skin and visceral targets.

Neurons in lamina VI receive inputs from largediameter fibers that innervate muscles and joints. These neurons are activated by innocuous joint movement and do not contribute to the transmission of nociceptive information. In contrast, many neurons located in laminae VII and VIII, the intermediate and ventral regions of the spinal cord, do respond to noxious stimuli. These neurons typically have complex response properties because the inputs from nociceptors to these neurons are conveyed through many intervening synapses. Neurons in lamina VII often respond to stimulation of either side of the body, whereas most dorsal horn neurons receive unilateral input. The activation of lamina VII neurons is therefore thought to contribute to the diffuse quality of many pain conditions.

Nociceptive sensory neurons that activate neurons in the dorsal horn of the spinal cord release two major classes of neurotransmitters. Glutamate is the primary neurotransmitter of all primary sensory neurons, regardless of sensory modality. Neuropeptides are released as cotransmitters by many nociceptors with unmyelinated axons. These peptides include substance P, calcitonin gene–related peptide (CGRP), somatostatin, and galanin (Figure 24–5). Glutamate is stored in small, electron-lucent vesicles, whereas peptides are sequestered in large, dense-core vesicles at the central terminals of nociceptive sensory neurons (Figure 24–6). Separate storage sites permit these two classes of neurotransmitters to be released under different physiological conditions.

Of the neuropeptides expressed by nociceptive sensory neurons, the actions of substance P, a member of the neurokinin peptide family, have been studied in most detail. Substance P is released from the central terminals of nociceptive afferents in response to tissue injury or after intense stimulation of peripheral nerves. Its interaction with neurokinin receptors on dorsal horn neurons elicits slow excitatory postsynaptic potentials that prolong the depolarization elicited by glutamate. Although the physiological actions of glutamate and neuropeptides on dorsal horn neurons are different, these transmitters act coordinately to regulate the firing properties of dorsal horn neurons.

There is no efficient means for peptide reuptake into nerve terminals, so neuropeptides released from sensory terminals diffuse over a greater distance than glutamate and thus have excitatory influences on many dorsal horn neurons in the immediate vicinity of the release site. This diffuse signaling system may contribute to the poorly localized character of many pain conditions. In addition, the levels of neuropeptide expression in primary nociceptive neurons are elevated in some pathological conditions. Such reactive changes in peptide expression may contribute to the enhanced excitability of dorsal horn neurons that accompanies some chronic pain states.

Details of the interaction of neuropeptides with their receptors on dorsal horn neurons have suggested strategies for pain regulation. Infusion of substance P coupled to a neurotoxin into the dorsal horn of experimental animals results in selective destruction of neurons that express neurokinin receptors. Animals treated in this way fail to develop the central sensitization that is normally associated with peripheral injury. This method of neuronal ablation is more selective than traditional surgical interventions such as partial spinal cord transection (anterolateral cordotomy) and is being explored as a treatment for patients suffering from chronic pain syndrome.

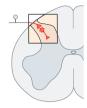

Hyperalgesia Has Both Peripheral and Central Origins

Up to this point we have considered the mechanisms that convey noxious signals in the normal physiological state. But the normal process of sensory signaling can be dramatically altered when peripheral tissue is damaged, resulting in an increase in pain sensitivity or hyperalgesia. This condition can be elicited by sensitizing peripheral nociceptors through repetitive exposure to noxious mechanical stimuli (Figures 24–7).

The sensitization is triggered by a complex mix of chemicals released from damaged cells that accumulate at the site of tissue injury. This cocktail contains peptides and proteins such as bradykinin, substance P, and nerve growth factor, as well as molecules such as ATP, histamine, serotonin, prostaglandins, leukotrienes, and acetylcholine. Many of these chemical mediators are released from distinct cell types, but together they act to decrease the threshold of nociceptor activation.

Where do these chemicals come from and what exactly do they do? Histamine is released from mast cells after tissue injury and activates polymodal nociceptors. The lipid anandamide, an endogenous cannabinoid agonist, is released under conditions of inflammation, activates the TRPV1 channel, and may trigger pain associated with inflammation. ATP, acetylcholine, and serotonin are released from damaged endothelial cells and platelets; they act indirectly to sensitize nociceptors by triggering the release of chemical agents such as prostaglandins and bradykinin from peripheral cells. Bradykinin is one of the most active pain-producing agents. Its potency stems in part from the fact that it directly activates A δ and C nociceptors as well as increasing the synthesis and release of prostaglandins from nearby cells.

Damaged cells also release prostaglandins, metabolites of arachidonic acid that are generated through the activity of cyclooxygenase (COX) enzymes that cleave arachidonic acid. The COX2 enzyme is preferentially induced under conditions of peripheral inflammation, contributing to enhanced pain sensitivity. The enzymatic pathways of prostaglandin synthesis are targets

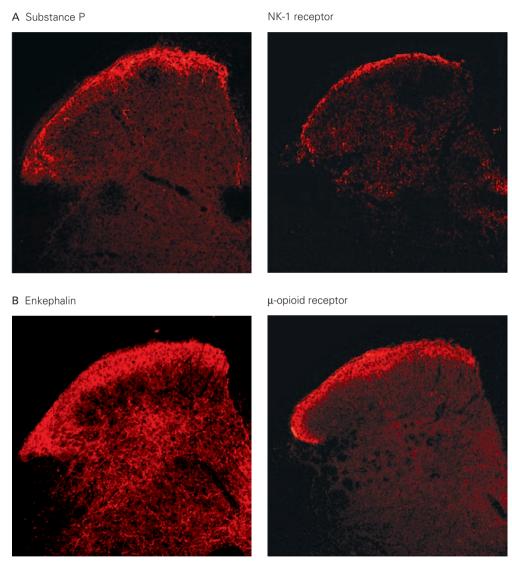

Figure 24–5 Neuropeptides and their receptors in the superficial dorsal horn of the rat spinal cord. (Images from A. Basbaum, reproduced with permission.)

A. Substance P is concentrated in the terminals of primary sensory neurons in the superficial dorsal horn. Its receptor, neurokinin-1 antagonist (NK1) is also expressed by neurons in the superficial dorsal horn.

B. Enkephalin is localized in interneurons and found in the same region of the dorsal horn as terminals containing substance P. The $\mu\text{-}opioid$ receptor for enkephalins is expressed by neurons in the superficial dorsal horn and also in sensory afferent terminals.

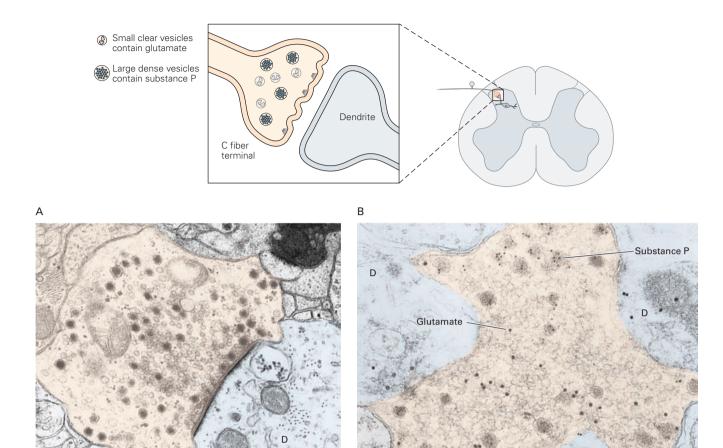

Figure 24–6 Transmitter storage in the synaptic terminals of primary nociceptive neurons in the dorsal spinal cord.

A. The terminal of a C fiber on the dendrite (D) of a dorsal horn neuron has two classes of synaptic vesicles that contain different transmitters. Small electron-lucent vesicles contain

glutamate while large dense-cored vesicles hold neuropeptides. (Image from H. J. Ralston III, reproduced with permission.)

of commonly used analgesic drugs. Aspirin and other nonsteroidal anti-inflammatory analgesics are effective in controlling pain because they block the activity of most COX enzymes, reducing prostaglandin synthesis. The drug acetaminophen appears to exert its analgesic effects through selective inhibition of COX3.

Tissue inflammation also results from peripheral injury. The cardinal signs of inflammation are heat (calor), redness (rubor), and swelling (tumor). Heat and redness result from the dilation of peripheral blood vessels, whereas swelling results from plasma extravasation, a process in which proteins, cells, and fluids are able to penetrate post-capillary venules. Release of the neuropeptides substance P and CGRP from the peripheral terminals of C fibers can elicit each of these pathological responses. Because this form of

inflammation depends on neural activity, it has been termed *neurogenic inflammation* (Figure 24–8).

The release of substance P and CGRP from the peripheral terminals of sensory neurons is also responsible for the *axon reflex*, a physiological process characterized by vasodilation in the vicinity of a cutaneous injury. Pharmacological antagonists of substance P are able to block neurogenic inflammation and vasodilation in humans; this discovery illustrates how knowledge of nociceptive mechanisms has relevance for improved clinical therapies for pain.

In addition to these small molecules and peptides, neurotrophins are causative agents in pain. Nerve growth factor (NGF) is particularly active in inflammatory pain states; the synthesis of NGF is upregulated in many inflamed peripheral tissues (Figure 24–9).

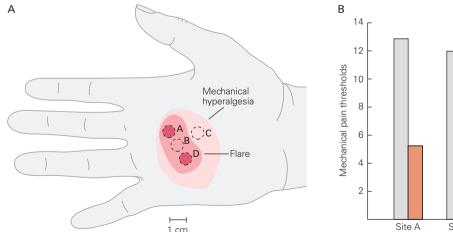

NGF-neutralizing molecules are effective analgesic agents in animal models of persistent pain. Indeed, inhibition of NGF function and signaling blocks pain sensation as effectively as COX inhibitors and opiates. The expression of brain derived neurotrophic factor (BDNF) is also elevated in nociceptive neurons under conditions of inflammatory and neuropathic pain. BDNF is transported to the central terminals of the primary afferents in the spinal dorsal horn, where its release enhances the response of dorsal horn neurons to painful stimuli (Figure 24-9). Drugs that block BDNF expression in nociceptive neurons may therefore be useful as analgesics.

What accounts for the enhanced sensitivity of dorsal horn neurons to nociceptor signals? Under conditions of persistent injury C fibers fire repetitively and the response of dorsal horn neurons increases progressively (Figure 24–10A). The gradual enhancement in the excitability of dorsal horn neurons has been termed "windup" and is thought to involve N-methyl-D-aspartate (NMDA)-type glutamate receptors (Figure 24–10B).

Repeated exposure to noxious stimuli therefore results in long-term changes in the response of dorsal horn neurons through mechanisms that are similar to those underlying the long-term potentiation of synaptic responses in many circuits in the brain. In essence these prolonged changes in the excitability of dorsal horn neurons constitute a "memory" of the state of C fiber input. This phenomenon has been termed central sensitization to distinguish it from sensitization at the peripheral terminals of the dorsal horn neurons, a process that involves activation of the enzymatic pathways of prostaglandin synthesis.

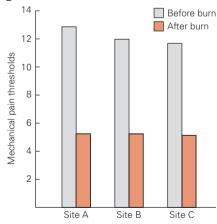

The sensitization of dorsal horn neurons also involves recruitment of second-messenger pathways and activation of protein kinases that have been implicated in memory storage in other regions of the central nervous system. One consequence of this enzymatic cascade is the expression of immediate-early genes that encode transcription factors such as *c-fos*, which are thought to activate effector proteins that sensitize dorsal horn neurons to sensory inputs.

In certain clinical conditions alterations in the excitability of dorsal horn neurons can decrease pain thresholds and lead to spontaneous pain. One dramatic illustration of this phenomenon is phantom limb pain, the persistent sensations of pain that appear to originate from the region of an amputated limb (Figure 24–11). Until recently limb amputation was performed solely with a general anesthetic on the assumption that this alone should be sufficient to eliminate memory of the traumatic surgical procedure. Surgeons found, however, that even under general anesthesia the spinal cord "experiences" the insult of the surgical procedure, presumably because of ongoing central sensitization. So to reduce the risk of phantom limb pain, amputation

A. Mechanical thresholds for pain were recorded at sites A, B, and C before and after burns at sites A and D. The areas of reddening (flare) and mechanical hyperalgesia resulting from the burns are shown on the hand of one subject. In all subjects

the area of mechanical hyperalgesia was larger than the area of flare. Mechanical hyperalgesia was present even after the flare disappeared.

B. Mean mechanical pain thresholds before and after burns. The mechanical threshold for pain is significantly decreased after the burn.

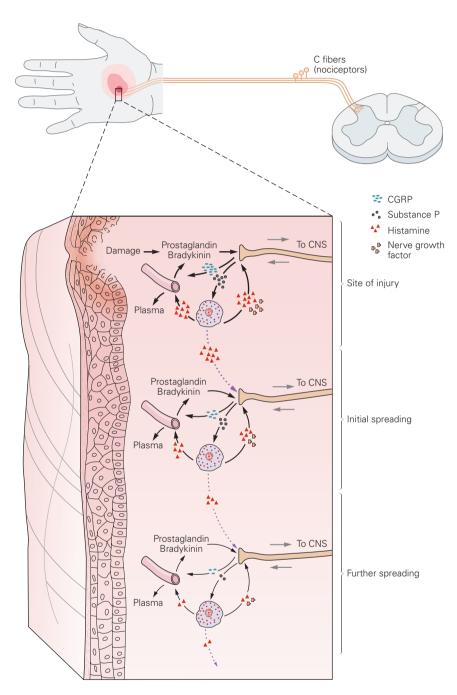

Figure 24–8 Neurogenic inflammation. Injury or tissue damage releases bradykinin and prostaglandins, which activate or sensitize nociceptors. Activation of nociceptors leads to the release of substance P and CGRP (calcitonin gene–related peptide). Substance P acts on mast cells in the vicinity of sensory endings to evoke degranulation and the release of histamine, which directly excites nociceptors. Substance P produces

plasma extravasation, and CGRP produces dilation of peripheral blood vessels; the resultant edema causes additional liberation of bradykinin. These mechanisms also occur in healthy tissue, where they cause secondary or spreading hyperalgesia. now includes interventions that block the central sensitization of dorsal horn neurons. General anesthesia is often supplemented with direct spinal administration of an analgesic agent or local administration of anesthetic at the injury site.

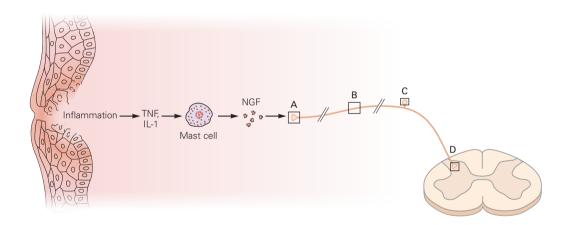

Nociceptive Information Is Transmitted from the Spinal Cord to the Thalamus

Five Major Ascending Pathways Convey **Nociceptive Information**

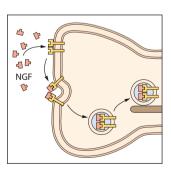

Five major ascending pathways—the spinothalamic, spinoreticular, spinomesencephalic, cervicothalamic, and spinohypothalamic tracts—contribute to the central processing of nociceptive information.

The spinothalamic tract is the most prominent ascending nociceptive pathway in the spinal cord. It includes the axons of nociception-specific, thermosensitive, and wide-dynamic-range neurons in laminae I and V through VII of the dorsal horn. These axons cross the midline of the spinal cord at their segment of origin and ascend in the anterolateral white matter before terminating in thalamic nuclei (Figure 24–12). The spinothalamic tract has a crucial role in the transmission of nociceptive information. Electrical stimulation of the tract is sufficient to elicit the sensation of pain; conversely, lesioning this tract (anterolateral cordotomy) can result in a marked reduction in pain sensation on the side of the body contralateral to that of the lesion.

The spinoreticular tract contains the axons of projection neurons in laminae VII and VIII. This tract ascends in the anterolateral quadrant of the spinal cord

B Retrograde transport of signaling endosomes

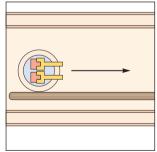

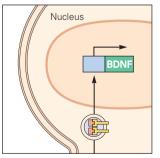

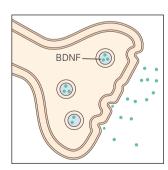

Figure 24–9 Neurotrophins are pain mediators. Local production of inflammatory cytokines such as interleukin-1 (IL-1) and tumor necrosis factor (TNF) promotes the synthesis and release of nerve growth factor (NGF) from several cell types in the periphery. NGF binds to TrkA receptors on primary nociceptive terminals (A), triggering localized post-transitional

C Increased transcription of BDNF

D Central release of BDNF

changes in expression of ion channels that increase nociceptor excitability. Retrograde transport of signaling endosomes to the cell body (B) results in enhanced expression of brain derived neurotrophic factor (BDNF) (C), and its release from sensory terminals in the spinal cord (D) further increases excitability and facilitates the activation of dorsal horn neurons.

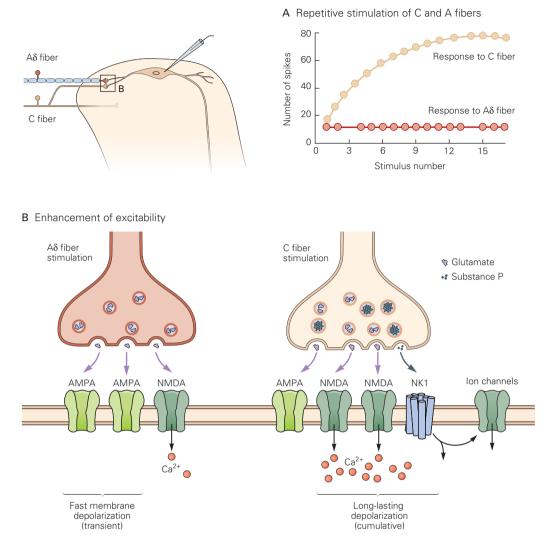

Figure 24–10 Mechanisms for enhanced excitability of dorsal horn neurons.

A. Typical responses of a dorsal horn neuron in the rat to electrical stimuli delivered transcutaneously at a frequency of 1 Hz. With repetitive stimulation the long-latency component evoked by a C fiber increases gradually, whereas the short-latency component evoked by an A fiber remains constant.

B. The dorsal horn neuron receives monosynaptic input from mechanoreceptors (A fibers) and polysynaptic input from nociceptors (C fibers). Elevation of Ca^{2+} in the presynaptic terminal leads to increased release of glutamate and substance P. Activation of the postsynaptic α -amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA)-type glutamate receptors by A fibers causes a fast transient membrane depolarization,

which relieves the Mg²⁺ block of the *N*-methyl-p-aspartate (NMDA)-type receptors. Activation of the postsynaptic NMDA-type receptors and neurokinin-1 (NK1) antagonist receptors by C fibers generates a long-lasting cumulative depolarization. The cytosolic Ca²⁺ concentration in the dorsal horn neuron increases because of Ca²⁺ entry through the NMDA-type and AMPA-type channels and voltage-sensitive Ca²⁺ channels. The elevated Ca²⁺ and activation of NK1 receptors through second-messenger systems enhances the performance of the NMDA-type receptors. Activation of NK1 receptors, cumulative depolarization, elevated cytosolic Ca²⁺, and other factors regulate the behavior of ion channels responsible for action potentials, resulting in enhanced excitability.

and terminates in both the reticular formation and the thalamus (Figure 24–12). The axons of spinoreticular tract neurons do not cross the midline.

The spinomesencephalic (or spinoparabrachial) tract contains the axons of projection neurons in laminae

I and V. Information transmitted along this tract is thought to contribute to the affective component of pain. This tract projects in the anterolateral quadrant of the spinal cord to the mesencephalic reticular formation and periaqueductal gray matter (Figure 24–12).

Axons in this tract also project to the parabrachial nucleus. Neurons of the parabrachial nucleus project to the amygdala, a key nucleus of the limbic system that regulates emotional states. Many of the axons of this pathway course through the dorsal part of the lateral funiculus rather than in the anterolateral quadrant. In surgical procedures designed to relieve pain, such as anterolateral cordotomy, the sparing of these fibers may explain the persistence or recurrence of pain after surgery.

The *cervicothalamic tract* runs in the lateral white matter of the upper two cervical segments of the spinal cord and contains the axons of neurons of the lateral cervical nucleus, which receives input from neurons in laminae III and IV of the dorsal horn. Most axons in the cervicothalamic tract cross the midline and ascend in the medial lemniscus of the brain stem, terminating in midbrain nuclei and in the ventroposterior lateral and posteromedial nuclei of the thalamus. Other neurons in laminae III and IV send their axons directly into the

to higher centers. (Adapted, with permission, from Willis 1985.)

dorsal columns and terminate in the cuneate and gracile nuclei of the medulla.

The *spinohypothalamic tract* contains the axons of neurons found in laminae I, V, and VIII of the dorsal horn in the spinal cord. These axons project to hypothalamic nuclei that serve as autonomic control centers involved in the regulation of the neuroendocrine and cardiovascular responses that accompany pain syndromes.

Several Thalamic Nuclei Relay Nociceptive Information to the Cerebral Cortex

The thalamus contains several relay nuclei that participate in the central processing of nociceptive information. Two of the most important regions of the thalamus are the lateral and medial nuclear groups.

The *lateral nuclear group* comprises the ventroposterior medial nucleus, the ventroposterior lateral nucleus, and the posterior nucleus. These three nuclei receive inputs through the spinothalamic tract from nociception-specific and wide-dynamic-range neurons in laminae I and V of the dorsal horn. The lateral thalamus is thought to be concerned with the processing of information about the precise location of an injury, information usually conveyed to consciousness as acute pain. Consistent with this view, neurons in the lateral thalamic nuclei have small receptive fields, matching those of the presynaptic spinal neurons.

Injury to the spinothalamic tract and its thalamic targets causes a severe form of pain termed *central pain*. An infarct in a small region of the ventroposterolateral thalamus produces the perception of a spontaneous burning pain, together with other abnormal sensations

(called dysesthesias) that are perceived as originating from diverse regions of the body. This constellation of abnormal percepts has been termed the Dejerine-Roussy syndrome. Electrical stimulation of the thalamus can also result in intense pain. In one dramatic clinical case, electrical stimulation of the thalamus rekindled sensations of angina pectoris that were so realistic that the anesthesiologist thought the patient was experiencing a heart attack. This and other clinical observations suggest that in chronic pain conditions there is a fundamental change in thalamic and cortical circuitry.

The *medial nuclear group* of the thalamus comprises the central lateral nucleus of the thalamus and the intralaminar complex. Its major input is from neurons in laminae VII and VIII of the dorsal horn. The pathway to the medial thalamus was the first spinothalamic projection evident in the evolution of mammals and is therefore known as the paleospinothalamic tract. It is also sometimes referred to as the spinoreticulothalamic tract because it includes indirect connections through the reticular formation of the brain stem. The projection from the lateral thalamus to the ventroposterior lateral and medial nuclei is most developed in primates, and is termed the neospinothalamic tract. Many neurons in the medial thalamus respond optimally to noxious stimuli and project widely to the basal ganglia and different cortical areas.

Pain Is Controlled by Cortical Mechanisms

Cingulate and Insular Areas Are Active During the Perception of Pain

Until recently research on the central processing of pain concentrated on the thalamus. But pain is a complex perception that involves many cortical areas whose activity is influenced critically by the context in which the noxious stimulus is presented, as well as by an individual's prior experience.

Neurons in several areas of the cerebral cortex respond to nociceptive input. In the somatosensory cortex neurons typically have small receptive fields and may not contribute greatly to the diffuse perception of aches and pains that characterize most clinical syndromes. The cingulate gyrus and insular cortex contain neurons that are activated strongly and selectively by nociceptive somatosensory stimuli (Box 24–1). The cingulate gyrus forms part of the limbic system and is thought to be involved in processing emotional states associated with pain. The insular cortex receives direct projections from the thalamus, specifically the medial

nuclei and the ventroposterior medial nucleus. Neurons in the insular cortex process information about the internal state of the body and contribute to the autonomic component of pain responses.

Patients with lesions of the insular cortex present the striking syndrome of asymbolia for pain: They perceive noxious stimuli as painful and can distinguish sharp from dull pain but fail to display appropriate emotional responses. These observations implicate the insular cortex as an area in which the sensory, affective, and cognitive components of pain are integrated.

Pain Perception Is Regulated by a Balance of Activity in Nociceptive and Non-Nociceptive Afferent Fibers

Many projection neurons in the dorsal horn of the spinal cord respond selectively to noxious inputs, but others receive convergent inputs from both nociceptive and non-nociceptive afferents. The concept that the convergence of sensory inputs onto spinal projection neurons regulates pain processing first emerged in the 1960s.

Ronald Melzak and Patrick Wall proposed that the relative balance of activity in nociceptive and non-nociceptive afferents might influence the transmission and perception of pain. In particular, they proposed that activation of non-nociceptive sensory neurons closes a "gate" for central transmission of nociceptive signals that can be opened by the activation of nociceptive sensory neurons. In the original and simplest form of this gate-control theory the interaction between large and small fibers occurred at the first possible site of convergence on projection neurons in the dorsal horn of the spinal cord (Figure 24–14). We now know that such interactions can also occur at many supraspinal relay centers and the strict anatomical predictions of the gate-control theory remain to be established.

Nevertheless, the core concept of convergence of different sensory modalities has provided an important basis for the design of new pain therapies. Viewed in its broadest sense, the convergence of high- and low-threshold inputs at spinal or supraspinal sites provided a plausible explanation for several empirical observations about the perception of pain. The shaking of the hand that follows a hammer blow or burn is a reflexive behavior and may alleviate pain by activating large-diameter afferents that suppress the central transmission of noxious stimuli.

The idea of convergence also helped to promote the use of transcutaneous electrical nerve stimulation (TENS) and dorsal column stimulation for the relief of pain. With TENS, stimulating electrodes placed

Box 24–1 Localizing Illusory Pain in the Cerebral Cortex

Thunberg's illusion, first demonstrated in 1896, is a strong, often painful heat felt after placing the hand on a grill of alternating warm and cool bars (Figure 24–13A).

This illusory sensation occurs because two classes of neurons in the ascending spinothalamic tract, those sensitive to innocuous or noxious cold, respond differently to the grill. This finding has led to a model of pain perception based on a central disinhibition or unmasking process in the cerebral cortex (Figure 24–13B).

The model predicts perceptual similarities between grill-evoked and cold-evoked pain, a prediction that has been verified psychophysically. The thalamocortical integration of pain and temperature stimuli can explain the burning sensation felt when nociceptors are activated by cold.

To identify the anatomical site of the unmasking phenomenon described above, positron emission tomography (PET) was used to compare the cortical areas activated by Thunberg's grill with those activated by cool, warm, noxious cold, and noxious heat stimuli separately. All thermal stimuli activate the insula and somatosensory cortices. The anterior cingulate cortex is activated by Thunberg's grill and by noxious heat and cold, but not by discrete warm and cool stimuli (Figure 24–13C).

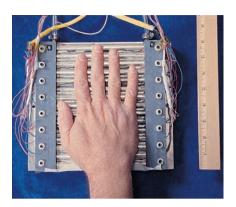

Figure 24–13A Thunberg's thermal grill. The stimulus surface (20 × 14 cm) is made of 15 sterling silver bars, each 1 cm wide, set approximately 3 mm apart. Underneath each bar are three longitudinally spaced thermoelectric (Peltier) elements (1 cm²), and on top of each bar is a thermocouple. Alternate (even- and odd-numbered) bars can be controlled independently. (Adapted, with permission, from Craig and Bushnell 1994; Craig et al. 1996.)

at peripheral locations activate large-diameter afferent fibers that overlap the area of injury and pain. The region of the body in which pain is reduced maps to those segments of the spinal cord in which nociceptive and non-nociceptive afferents from that body region terminate. This makes intuitive sense: You do not shake your left leg to relieve pain in your right arm.

Electrical Stimulation of the Brain Produces Analgesia

Several sites of endogenous pain regulation are located in the brain. One effective means of suppressing nociception involves stimulation of the periaqueductal gray region, the area of the midbrain that surrounds the

Figure 24-13B A model of regulation of pain perception. Excitation of nociceptive spinothalamic neurons by cool stimuli does not produce pain, presumably because coolspecific spinothalamic neurons exert a suppressive action on nociceptors. The grill stimulus has a similar effect but excites the cool-specific cells to a lesser extent, thus reducing their suppressive effect on cold pain. "Medial STT" refers to skin temperature test (STT) projections to the medial dorsal nucleus of the thalamus; "lateral STT" refers to spinothalamic axons in the middle of the lateral funiculus, as opposed to the ventral or anterior STT projections, which lie in the anterior funiculus. (MD_{vc}, ventral caudal part of medial dorsal nucleus; VM_{PO}, ventroposterior medial nucleus.) (Adapted, with permission, from Craig and Bushnell 1994; Craig et al. 1996.)

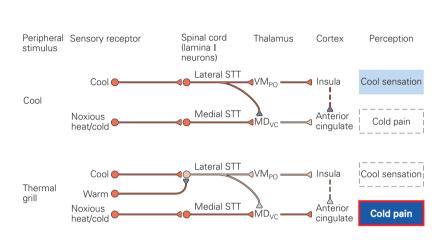

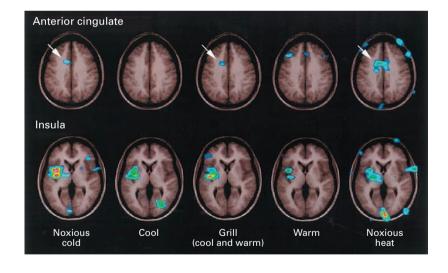

Figure 24–13C Cortical areas activated by Thunberg's grill. The anterior cingulate and insula regions of the cerebral cortex are activated when the hand is placed on the grill but not when warm and cool stimuli are applied separately. (Adapted, with permission, from Craig and Bushnell 1994; Craig et al. 1996.)

third ventricle and the cerebral aqueduct. In experimental animals stimulation of this region elicits a profound and selective analgesia. This *stimulation-produced analgesia* is remarkably specific; animals still respond to touch, pressure, and temperature within the body area that exhibits analgesia, but they feel less pain. Indeed, stimulation-evoked analgesia has proved to be

an effective way of relieving pain in a limited number of human pain conditions.

Stimulation of the periaqueductal gray matter is able to block spinally mediated withdrawal reflexes that are normally evoked by noxious stimulation. Few of the neurons in the periaqueductal gray matter project directly to the dorsal horn of the spinal cord.

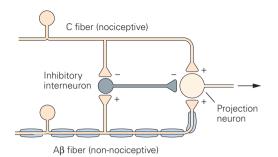

Figure 24–14 The gate-control theory of nociception. The gate-control hypothesis was proposed in the 1960s to account for the ability of low-threshold fiber activation to attenuate pain. The hypothesis focused on the interaction of neurons in the dorsal horn of the spinal cord: the nociceptive (C) and non-nociceptive (A β) sensory neurons, projection neurons, and inhibitory interneurons. In the original version of the model, as shown here, the projection neuron is excited by both classes of sensory neurons and inhibited by interneurons in the superficial dorsal horn. The two classes of sensory fibers also terminate on the inhibitory interneurons; the C-fibers inhibit the interneurons, thus increasing the activity of the projection neuron, while the A β fibers excite the interneurons, thus suppressing the output of the projection neurons.

Most make excitatory connections with neurons of the rostroventral medulla, including serotonergic neurons in a midline region called the nucleus raphe magnus, or neurons of the nuclei of the raphe complex. The axons of these serotonergic neurons project through the dorsal region of the lateral funiculus to the spinal cord, where they form inhibitory connections with neurons in laminae I, II, and V of the dorsal horn (Figure 24–15). Stimulation of the rostroventral medulla thus inhibits the firing of many classes of dorsal horn neurons, including projection neurons of the spinothalamic tract that convey afferent nociceptive signals.

A second major monoaminergic descending system can also suppress the activity of nociceptive neurons in the dorsal horn. This noradrenergic system originates in the locus ceruleus and other nuclei of the medulla and pons. These projections inhibit neurons in laminae I and V of the dorsal horn through direct and indirect synaptic actions.

Opioid Peptides Contribute to Endogenous Pain Control

Since discovery by the Sumerians in 3300 BC, the opium poppy and its active ingredients, opiates such as morphine and codeine, have been recognized as powerful analysesic agents. Over the past two decades

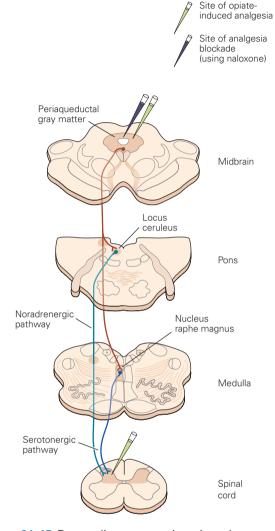

Figure 24–15 Descending monoaminergic pathways regulate nociceptive relay neurons in the spinal cord. A serotonergic pathway arises in the nucleus raphe magnus and projects through the dorsolateral funiculus to the dorsal horn of the spinal cord. A noradrenergic system arises in the locus ceruleus and other nuclei in the pons and medulla. (See Figure 46–2 for the locations and projections of monoaminergic neurons.) In the spinal cord these descending pathways inhibit nociceptive projection neurons through direct connections as well as through interneurons in the superficial layers of the dorsal horn. Both the sertonergic nucleus raphe magnus and noradrenergic nuclei receive input from neurons in the periaqueductal gray region. Sites of opioid peptide expression and actions of exogenously administered opioids are shown.

we have begun to understand many of the molecular mechanisms and neural circuits through which opiates exert their analgesic actions. In addition, we have come to realize that the neural networks involved in stimulation-produced and opiate-induced analgesia are intimately related.

Two key discoveries led to these advances. The first was the recognition that morphine and other opiates interact with specific receptors on neurons in the spinal cord and brain. The second was the isolation of endogenous neuropeptides with opiate-like activities at these receptors. The observation that the opiate antagonist naloxone blocks stimulation-produced analgesia provided the first clue that the brain contains endogenous opioids.

Endogenous Opioid Peptides and Their Receptors Are Distributed in Pain-Modulatory Systems

Opioid receptors fall into four major classes: mu (μ), delta (δ), kappa (κ), and orphanin FQ. The genes encoding each of these receptor types constitute a subfamily of G protein-coupled receptors. The μ receptors are particularly diverse; numerous μ receptor isoforms have been identified, many with different patterns of expression. This finding has prompted a search for analgesic drugs that target specific isoforms.

The opioid receptors were originally defined on the basis of the binding affinity of different agonist compounds. Morphine and other opioid alkaloids are potent agonists at μ receptors, and there is a tight correlation between the potency of an analgesic and its affinity of binding to μ receptors. Mice in which the gene for the μ receptor has been inactivated are insensitive to morphine and other opiate agonists. Many opiate antagonist drugs, such as naloxone, also bind to the μ receptor and compete with morphine for receptor occupancy without activating receptor signaling.

The μ receptors are highly concentrated in the superficial dorsal horn of the spinal cord, the ventral medulla, and the periaqueductal gray matter, important anatomical sites for the regulation of pain. Nevertheless, like other classes of opioid receptors, they are also found at many other sites in the central and peripheral nervous systems. Their widespread distribution explains why systemically administered morphine influences many physiological processes in addition to the perception of pain.

The discovery of opioid receptors and their expression by neurons in the central and peripheral nervous systems led to the definition of four major classes of endogenous opioid peptides, each interacting with a specific class of opioid receptors (Table 24–1).

Table 24–1 Four Major Classes of Endogenous Opioid Peptides

Propeptide	Peptide(s)	Preferential receptor
POMC	β-endorphin Endomorphin-1 Endomorphin-2	μ/δ μ μ
Proenkephalin	Met-enkephalin Leu-enkephalin	δ δ
Prodynorphin	Dynorphin A Dynorphin B	κ κ
Pro-orphanin FQ	Orphanin FQ	Orphan receptor

Three classes—the enkephalins, β -endorphins, and dynorphins—are the best characterized. These peptides are formed from large polypeptide precursors by enzymatic cleavage (Figure 24–16) and encoded by distinct genes. Despite differences in amino acid sequence, each contains the sequence Tyr-Gly-Gly-Phe. There are two enkephalins, leucine and methionine enkephalin, which are closely related small peptides. β-endorphin is a cleavage product of a precursor that also generates the active peptide adrenocorticotropic hormone (ACTH). Both β-endorphin and ACTH are synthesized by cells in the pituitary and are released into the bloodstream in response to stress. Dynorphins are derived from the polyprotein product of the dynorphin gene. Enkephalins are active at both μ and δ receptors, whereas dynorphin is a relatively selective agonist of the k receptor. The fourth endogenous opioid peptide is orphanin FQ or nociceptin (OFQ/N1–17). This 17-amino acid peptide is related in sequence to dynorphin and binds to the OFQ/N receptor.

Members of the four classes of opioid peptides are distributed widely in the central nervous system and individual peptides are located at sites associated with the processing or modulation of nociceptive information. Neuronal cell bodies and axon terminals containing enkephalin and dynorphin are found in the dorsal horn of the spinal cord, particularly in laminae I and II, as well as in the rostral ventral medulla and the periaqueductal gray matter. Neurons that synthesize β -endorphin are confined primarily to the hypothalamus; their axons terminate in the periaqueductal gray region and on noradrenergic neurons in the brain stem. Orphanin FQ appears to participate in a broad range of other physiological functions.

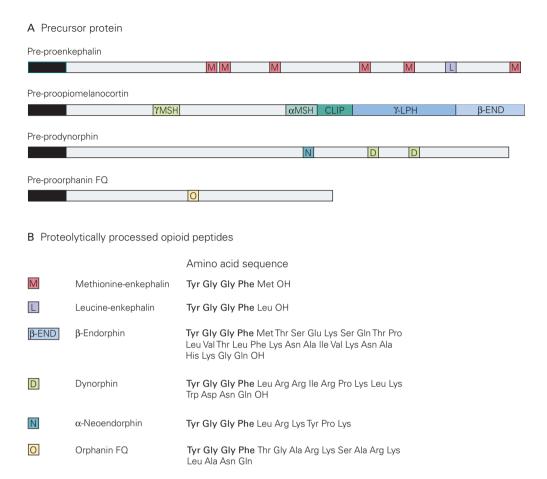

Figure 24–16 Four families of endogenous opioid peptides arise from large precursor polyproteins.

A. Each of the precursor molecules is cleaved by proteolytic enzymes to generate shorter, biologically active peptides, some of which are shown in this diagram. The proenkephalin precursor protein contains multiple copies of methionine-enkephalin (M), leucine-enkephalin (L), and several extended enkephalins. Proopiomelanocortin (POMC) contains β -endorphin, melanocyte-stimulating hormone (MSH), adrenocorticotropic hormone

(ACTH), and corticotropin-like intermediate-lobe peptide (CLIP). The prodynorphin precursor can produce dynorphin (D) and α -neoendorphin (N). The pro-orphanin precursor contains the orphanin FQ peptide (O). The black domains indicate a signal peptide.

B. Amino acid sequences of proteolytically processed bioactive peptides. The amino acid residues shown in bold type mediate interaction with opioid receptors. (Adapted, with permission, from Fields 1987.)

Morphine Controls Pain by Activating Opioid Receptors

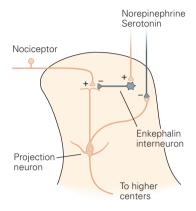

Microinjection of low doses of morphine or other opiates directly into specific regions of the rat brain produces a powerful analgesia. The periaqueductal gray region is among the most sensitive sites, but local administration of morphine into other regions, including the spinal cord, also elicits a powerful analgesia.

Morphine-induced analgesia can be blocked by injection of the opiate antagonist naloxone into the periaqueductal gray region or the nucleus raphe magnus (Figure 24–15). In addition, bilateral transection of

the dorsal lateral funiculus in the spinal cord blocks analgesia induced by central administration of morphine. Thus the central analgesic actions of morphine involve the activation of descending pathways to the spinal cord.

In the spinal cord, as elsewhere, morphine acts by mimicking the actions of endogenous opioid peptides. The superficial dorsal horn of the spinal cord contains interneurons that express enkephalin and dynorphin, and the terminals of these neurons lie close to synapses formed by nociceptive sensory neurons and spinal projection neurons (Figure 24–17A). Moreover, the μ , δ , and κ receptors are located on the terminals of the

A Nociceptor circuitry in the dorsal horn

B Effects of opiates and opioids on nociceptor signal transmission

1 Sensory input alone

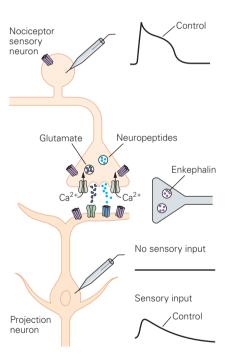

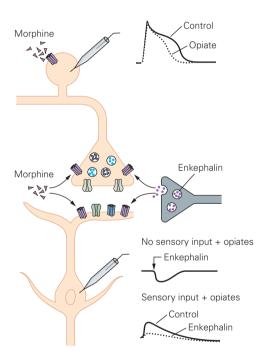

Figure 24–17 Local interneurons in the spinal cord integrate descending and afferent nociceptive pathways.

A. Nociceptive afferent fibers, local interneurons, and descending fibers interconnect in the dorsal horn of the spinal cord (see also Figure 24–3B). Nociceptive fibers terminate on second-order spinothalamic projection neurons. Local enkephalin-containing interneurons exert both pre- and postsynaptic inhibitory actions at these synapses. Serotonergic and noradrenergic neurons in the brain stem activate the local interneurons and also suppress the activity of the spinothalamic projection neurons.

2 Sensory input + opiates/opioids

B. Regulation of nociceptive signals at dorsal horn synapses. 1. Activation of a nociceptor leads to the release of glutamate and neuropeptides from the primary sensory neuron, producing an excitatory postsynaptic potential in the projection neuron. **2.** Opiates decrease the duration of the postsynaptic potential, probably by reducing Ca²⁺ influx and thus decreasing the release of transmitter from the primary sensory terminals. In addition, opiates hyperpolarize the dorsal horn neurons by activating a K⁺ conductance and thus decrease the amplitude of the postsynaptic potential in the dorsal horn neuron.

nociceptive sensory neurons as well as on the dendrites of dorsal horn neurons that receive afferent nociceptive input, thus placing endogenous opioid peptides in a strategic position to regulate sensory afferent input. The number of μ receptors on $A\delta$ nociceptors, which mediate fast and acute pain or "first pain", exceeds that on C fiber nociceptors, which mediate slow persistent pain or "second pain" (Figure 24–1). This may help to explain why morphine is more effective in the treatment of persistent rather than acute pains.

Opiates regulate nociceptive transmission at synapses in the dorsal horn through two main mechanisms. First, they increase membrane K⁺ conductances in the dorsal horn neurons, hyperpolarizing the neurons and thus increasing the threshold for activation. Second, by binding to receptors on presynaptic sensory terminals opiates inhibit the release of neurotransmitter and thus decrease the extent of activation of the postsynaptic dorsal horn neurons. The decrease in neurotransmitter release appears to result from a decrease in Ca²⁺ conductance and consequent reduction of Ca²⁺ entry into the sensory nerve terminal (Figure 24–17B).

Many of the side effects of opiates are caused by the activation of opiate receptors within the brain and periphery. Opiate receptors are expressed by muscles of the bowel and anal sphincter; their activation contributes to constipation. The activation of opiate receptors in the nucleus of the solitary tract is responsible for respiratory depression and cardiovascular side effects. Confining drug administration to the spinal cord or to the periphery can minimize the side effects of systemic opiates. The release of endogenous opioid peptides from chromaffin cells of the adrenal medulla or from immune cells that migrate into injury sites may normally be involved in regulating the activation of nociceptors. The presence of peripheral opioid receptors has potential clinical relevance. Prolonged relief of pain after arthroscopic surgery can be achieved by injection of morphine into joints at doses that are ineffective when administered systemically. This peripheral route of opiate administration significantly reduces the side effects of opiate drugs.

Because the dorsal horn of the spinal cord has a high density of opioid receptors, morphine injected into the cerebrospinal fluid of the spinal cord subarachnoid space interacts with these receptors to elicit a profound and prolonged analgesia. Local administration of morphine is now commonly used in the treatment of postoperative pain, notably the pain associated with Caesarean section during childbirth. In addition to producing prolonged analgesia, intrathecal injection of

morphine has fewer side effects because the drug does not diffuse far from its site of injection. Continuous local infusion of morphine to the spinal cord has also been used for the treatment of certain cancer pains.

Tolerance and Addiction to Opioids Are Distinct Phenomena

The chronic use of morphine invites major problems, most notably tolerance and addiction. The repeated use of morphine for pain relief can cause patients to develop resistance to the analgesic effects of the drug, with the consequence that progressively higher drug doses are required to achieve the same therapeutic effect.

What are the mechanisms underlying opiate tolerance? One theory holds that tolerance results from uncoupling of the opioid receptor from its G protein transducer. Nevertheless, the binding of naloxone to μ opiate receptors can precipitate withdrawal symptoms in tolerant subjects, suggesting that the opioid receptor is still active in the tolerant state. Tolerance may therefore also reflect a cellular response to the activation of opioid receptors, a response that counteracts the effects of the opiate and resets the system. Then, when the opiate is abruptly removed or naloxone is administered, this compensatory response is unmasked and withdrawal results.

Such physiological tolerance differs from addiction, a psychological craving for the drug. Psychological addiction almost never occurs when morphine is used to treat chronic pain.

An Overall View

Pain is a complex sensory state that reflects the integration of many sensory signals. More than most sensory modalities, its perception is influenced by emotional state and environmental contingency. Because pain is dependent on experience and varies so markedly from person to person, it remains notoriously difficult to treat.

Our understanding of the organization of central pain circuits, under both normal and pathological conditions, remains sadly incomplete. Nevertheless, over the past decade remarkable insights into the molecular mechanisms of peripheral pain transduction have developed, opening the way for new and more effective pain therapies.

First, human genetics and molecular biology have revealed that specific Na⁺ channels are expressed selectively by nociceptive sensory neurons, and that

mutation in the genes encoding one of these channels results in congenital insensitivity to pain while preserving other somatosensory modalities. These findings have prompted the search for small-molecule chemicals that can block nociceptor-specific Na⁺ channels and thereby serve as selective peripheral analgesics. Second, the discovery that TRP channels encode sensory responses to a range of temperatures—from burning cold to scalding hot—and the knowledge that capsaicin and other small molecules activate these channels in a selective manner, has led to the development of many small-molecule TRP channel antagonists, some of which may prove to be effective in clinical pain syndromes.

How noxious mechanical stimuli are transduced remains a mystery, and defining the nature of the ion channels involved in the mechanotransduction of noxious stimuli remains an important challenge.

The classical finding that the balance of activity in small- and large-diameter sensory fibers modulates the perception of pain prompted the use of transcutaneous and dorsal-column electrical stimulation in the control of certain types of peripheral pain. This along with the observation that stimulation of specific sites in the brain stem produces profound analgesia has fostered efforts to control pain by activating endogenous modulatory systems. For example, the knowledge that opiates applied directly to the spinal cord elicit a potent analgesia led to the localized administration of opiates in certain clinical conditions by intrathecal and epidural routes.

Nevertheless, the uncertainties about the basic anatomy and functional organization of pain pathways mean that for most central pain syndromes there are still no effective pain therapies. Future progress in pain therapy will therefore depend on defining the logic of brain circuits that transmit nociceptive signals under normal and pathological conditions.

Intrinsic Cortical Circuits Transform Neural Information

Visual Information Is Represented by a Variety of Neural Codes

An Overall View

We are so familiar with seeing, that it takes a leap of imagination to realize that there are problems to be solved. But consider it. We are given tiny distorted upside-down images in the eyes and we see separate solid objects in surrounding space. From the patterns of stimulation on the retina we perceive the world of objects and this is nothing short of a miracle.

-Richard L. Gregory, Eye and Brain, 1966

ost of our impressions of the world and our memories of it are based on sight. Yet the mechanisms that underlie vision are not at all obvious. How do we perceive form and movement? How do we distinguish colors? Identifying objects in complex visual environments is an extraordinary

computational achievement that artificial vision systems have yet to duplicate. Vision is used not only for object recognition but also for guiding our movements, and these separate functions are mediated by at least two parallel and interacting pathways.

The existence of parallel pathways in the visual system raises one of the central questions of cognition, the binding problem. How are different types of information carried by discrete pathways brought together into a coherent visual image?

Visual Perception Is a Constructive Process

Vision is often incorrectly compared to the operation of a camera. Unlike a camera, however, the visual system is able to create a three-dimensional representation of the world from the two-dimensional images on the retina. In addition, an object is perceived as the same under strikingly different visual conditions.

A camera reproduces point-by-point the light intensities in one plane of the visual field. The brain, in contrast, parses scenes into distinct components, separating foreground from background, to determine which light stimuli belong to one object and which to others. In doing so it uses previously learned rules about the structure of the world. In analyzing the incoming stream of visual signals the brain guesses at the scene presented to the eyes based on past experience.

This *constructive* nature of visual perception has only recently been fully appreciated. Earlier thinking about sensory perception was greatly influenced by the British empiricist philosophers, notably John Locke, David Hume, and George Berkeley, who thought of

perception as an atomistic process in which simple sensory elements, such as color, shape, and brightness, were assembled in an additive way, component by component. The modern view that perception is an active and creative process that involves more than just the information provided to the retina has its roots in the philosophy of Immanuel Kant and was developed in detail in the early 20th century by the German psychologists Max Wertheimer, Kurt Koffka, and Wolfgang Köhler, who founded the school of Gestalt psychology.

The German term *Gestalt* means configuration or form. The central idea of the Gestalt psychologists is that what we see about a stimulus—the perceptual interpretation we make of any visual object—depends not just on the properties of the stimulus but also on its context, on other features in the visual field. The Gestalt psychologists argued that the visual system processes sensory information about the shape, color, distance, and movement of objects according to computational rules inherent in the system. The brain has a way of looking at the world, a set of expectations that derives in part from experience and in part from built-in neural wiring.

Max Wertheimer wrote: "There are entities where the behavior of the whole cannot be derived from its individual elements nor from the way these elements fit together; rather the opposite is true: the properties of any of the parts are determined by the intrinsic structural laws of the whole." In the early part of the 20th century the Gestalt psychologists worked out the laws of perception that determine how we see, including similarity, proximity, and good continuation.

We see a uniform six-by-six array of dots as either rows or columns because of the brain's tendency to impose a pattern. Thus if the dots in each row are similar we are more likely to see a pattern of alternating rows (Figure 25–1A). If the dots in each column are closer together than those in the rows, we are more disposed to see a pattern of columns (Figure 25–1B). The principle of good continuation is an important basis for linking line elements into unified shapes (Figure 25–1C). It is also seen in the phenomenon of contour saliency, whereby smooth contours tend to pop out from complex backgrounds (Figure 25–1D).

An important step in object recognition is separating figure from background. At different moments the same elements in the visual field can be organized into a recognizable figure or serve as part of the background for other figures (Figure 25–2). Segmentation relies not only on certain geometric principles, but also on cognitive influences such as attention and expectation. Thus a priming stimulus or an internal representation of

object shape can facilitate the association of visual elements into a unified percept (Figure 25–3).

The brain analyzes a visual scene at three levels: low, intermediate, and high (Figure 25–4). At the lowest level, which we consider in the next chapter, visual attributes such as local contrast, orientation, color, and movement are discriminated. The intermediate level involves analysis of the layout of scenes and of surface properties, parsing the visual image into surfaces and global contours, and distinguishing foreground from background (see Chapter 27). The highest level involves object recognition (see Chapter 28). Once a scene has been parsed by the brain and objects recognized, the objects can be matched with memories of shapes and their associated meanings. Vision also has an important role in guiding body movement, particularly hand movement (see Chapter 29).

In vision as in other cognitive operations, various features—motion, depth, form, and color—occur together in a unified percept. This unity is achieved not by one hierarchical neural system but by multiple areas in the brain that are fed by at least two major interacting neural pathways. Because distributed processing is one of the main organizational principles in the neurobiology of vision, one must have a grasp of the anatomical pathways of the visual system to understand fully the physiological description of visual processing in later chapters.

In this chapter we lay the foundation for understanding the neural circuitry and organizational principles of the visual pathways. These principles apply quite broadly and are relevant not only for the multiple areas of the brain concerned with vision but also for other types of information processing by the brain.

Visual Perception Is Mediated by the Geniculostriate Pathway

Visual processing begins in the two retinae (see Chapter 26). The axons of the retinal ganglion cells, the projection neurons of the retina, form the optic nerve that extends to a midline crossing point, the optic chiasm. Beyond the chiasm fibers from the temporal hemiretinas proceed to the ipsilateral hemisphere; fibers from the nasal hemiretinas cross to the contralateral hemisphere (Figure 25–5). Because the temporal hemiretina of one eye sees the same half of the visual field (hemifield) as the nasal hemiretina of the other, the partial decussation of fibers at the chiasm ensures that all the information about each hemifield is processed in the visual cortex of the contralateral hemisphere.

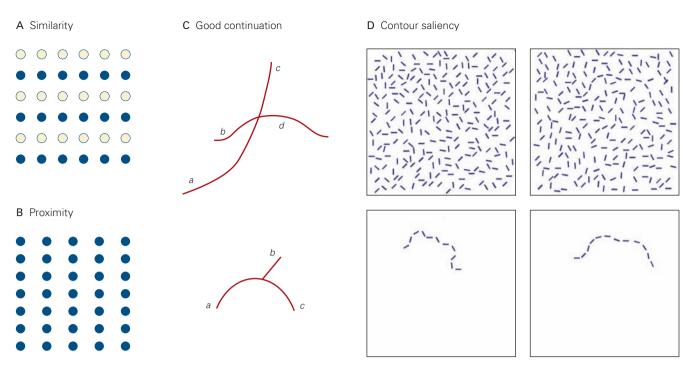

Figure 25–1 Organizational rules of visual perception. To link the elements of a visual scene into unified percepts, the visual system relies on organizational rules such as similarity, proximity, and good continuation.

A. The dots in each row have the same color, and thus, an overall pattern of alternating blue and white rows is perceived.

B. The dots in the columns are closer together than those in the rows, leading to the perception of columns.

C. Line segments are perceptually linked when they are collinear. In the top set of lines, one is more likely to see line

segment a as belonging with c rather than d. In the bottom set a and c are perceptually linked because they maintain the same curvature, whereas a and b appear to be discontinuous.

D. The principle of good continuation is also seen in contour saliency. On the right a smooth contour of line elements pops out from the background, whereas the jagged contour on the left is lost in the background. (Adapted, with permission, from Field, Hayes, and Hess 1993.)

Figure 25–2 Object recognition depends on the separation of foreground and background in a scene. Recognition of the white salamanders in this image depends on the brain's segmentation of the image, situating the white salamanders in the foreground and the brown and black salamanders in the background. The image also illustrates the role of higher influences in segmentation: One can consciously select any of the three colors as the foreground. (Reproduced, with permission, from M.C. Escher's "Symmetry Drawing E56" © 2010 The M.C. Escher Company-Holland. All rights reserved. www.mcescher. com.)

Figure 25–3 Expectation and perceptual task play a critical role in what is seen. It is difficult to segment the dark and white patches in this figure into foreground and background without additional information. After viewing the priming image on page 561, this figure immediately becomes recognizable. In this example higher-order representations of shape guide lower-order processes of segmentation. (Reproduced, with permission, from Porter 1954.)

Beyond the optic chiasm the axons from nasal and temporal hemiretinas carrying input from one hemifield join in the optic tract, which extends to the lateral geniculate nucleus of the thalamus. The lateral geniculate nucleus in primates consists of six layers, each of which receives input from either the ipsilateral or the contralateral eye. Because each layer contains a map of the contralateral hemifield, six concordant maps are stacked atop one another. The thalamic neurons then relay retinal information to the primary visual cortex.

The primary visual pathway is also called the geniculostriate pathway because it passes through the lateral geniculate nucleus on its way to the primary visual cortex, also known as the striate cortex because of the myelin-rich stripe that runs through its middle layers. A second pathway from the retina runs to the superior colliculus and is important in controlling eye movements. This pathway continues to the pontine formation in the brain stem and then to the extraocular motor nuclei. A third pathway extends from the retina to the pretectal area of the midbrain, where neurons mediate the pupillary reflexes that control the amount of light entering the eyes.

Each lateral geniculate nucleus projects to the primary visual cortex through a pathway known as the optic radiation (Figure 25–6A). These afferent fibers form a complete neural map of the contralateral visual field in the primary visual cortex. Beyond the striate cortex lie the extrastriate areas, a set of higher-order visual areas that are also organized as neural maps of the visual field. The preservation of the spatial arrangement of inputs from the retina is called retinotopy, and a neural map of the visual field is described as retinotopic or having a retinotopic frame of reference.

The primary visual cortex constitutes the first level of cortical processing of visual information. From there information is transmitted over two major pathways. A ventral pathway into the temporal lobe carries information about what the stimulus is, and a dorsal pathway into the parietal lobe carries information about where the stimulus is, information that is critical for guiding movement.

A major fiber bundle called the corpus callosum connects the two hemispheres, transmitting information across the midline. The primary visual cortex in either hemisphere represents slightly more than half the visual field, with the two hemifield representations overlapping at the vertical meridian. One of the functions of the corpus callosum is to unify the perception of objects spanning the vertical meridian by linking the cortical areas that represent opposite hemifields.

Form, Color, Motion, and Depth Are Processed in Discrete Areas of the Cerebral Cortex

In the late 19th and early 20th centuries the cerebral cortex was differentiated by the anatomist Korbinian Brodmann and others using anatomical criteria. The criteria included the size, shape, and packing density of neurons in the cortical layers and the thickness and density of myelin. The functionally distinct cortical areas we have considered heretofore correspond only loosely to Brodmann's classification. The primary visual cortex (V1) is identical to Brodmann's area 17. In the extrastriate cortex the secondary visual area, V2, corresponds to area 18. Beyond that, however, area 19 contains several functionally distinct areas that generally cannot be defined by anatomical criteria.

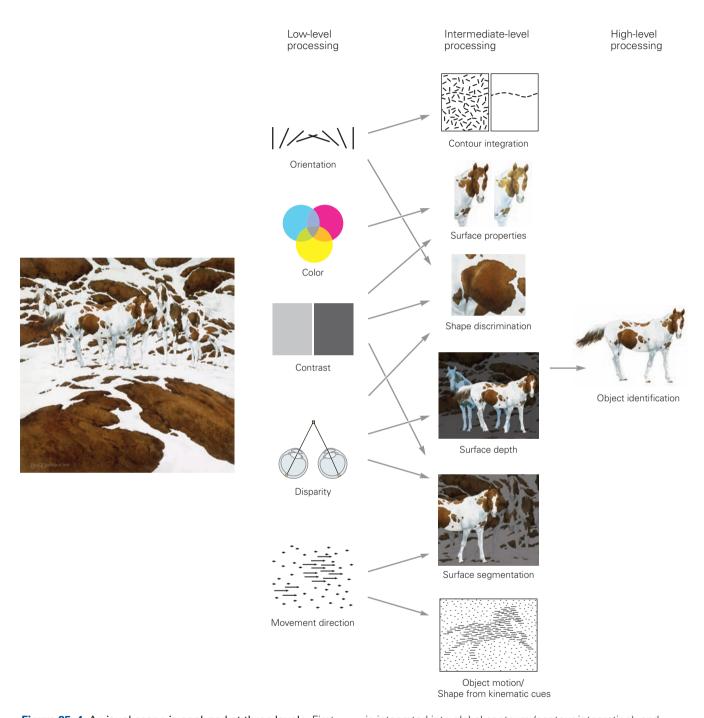

Figure 25–4 A visual scene is analyzed at three levels. First, simple attributes of the visual environment are analyzed (low-level processing). These low-level features are used to parse the visual scene (intermediate-level processing): Local visual features are assembled into surfaces, objects are segregated from background (surface segmentation), local orientation

is integrated into global contours (contour integration), and surface shape is identified from shading and kinematic cues. Finally, surfaces and contours are used to identify the object (high-level processing). (Images of horses reproduced, with permission, from *Pintos*, © Bev Doolittle, courtesy of The Greenwich Workshop, Inc., www.greenwichworkshop.com.)

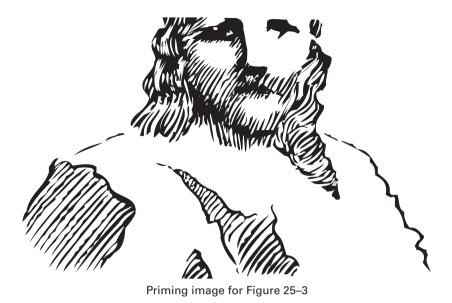

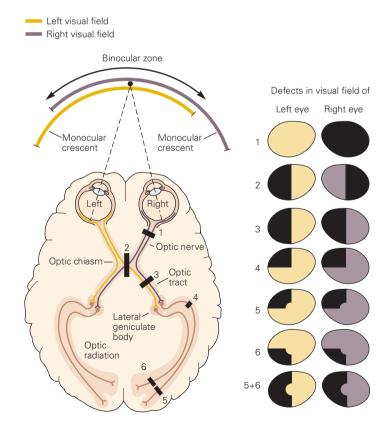

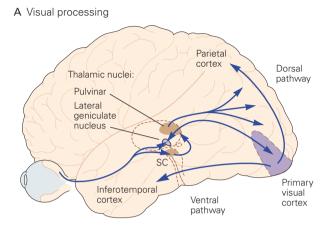

Figure 25–5 Representation of the visual field along the visual pathway. Each eye sees most of the visual field, with the exception of a portion of the peripheral visual field known as the monocular crescent. The axons of retinal neurons (ganglion cells) carry information from each visual hemifield along the optic nerve up to the optic chiasm, where fibers from the nasal hemiretina cross to the opposite hemisphere. Fibers from the temporal hemiretina stay on the same side, joining the fibers from the nasal hemiretina of the contralateral eye to form the optic tract. The optic tract carries information from the opposite visual hemifield originating in both eyes and projects into the lateral geniculate nucleus. Cells in this nucleus send their axons along the optic radiation to the primary visual cortex.

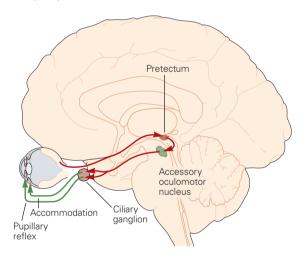

Lesions along the visual pathway produce specific visual field deficits, as shown on the right:

- 1. A lesion of an optic nerve causes a total loss of vision in one eye.
- 2. A lesion of the optic chiasm causes a loss of vision in the temporal half of each visual hemifield (bitemporal hemianopsia).
- **3.** A lesion of the optic tract causes a loss of vision in the opposite half of the visual hemifield (contralateral hemianopsia).
- **4.** A lesion of the optic radiation fibers that curve into the temporal lobe (Meyer's loop) causes loss of vision in the upper quadrant of the contralateral visual hemifield in both eyes (upper contralateral quadrantic anopsia).
- 5,6. Partial lesions of the visual cortex lead to deficits in portions of the contralateral visual hemifield. For example, a lesion in the upper bank of the calcarine sulcus (5) causes a partial deficit in the inferior quadrant, while a lesion in the lower bank (6) causes a partial deficit in the superior quadrant. The central area of the visual field tends to be unaffected by cortical lesions because of the extent of the representation of the fovea and the duplicate representation of the vertical meridian in the hemispheres.

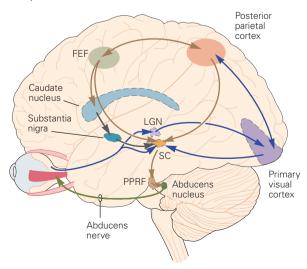

B Pupillary reflex and accommodation

C Eye movement (horizontal)

The number of functionally discrete areas of visual cortex varies between species. Macaque monkeys have more than 30 areas. Although not all visual areas in humans have yet been identified, the number is likely to be at least as great as in the macaque. If one includes oculomotor areas and prefrontal areas contributing to visual memory, almost half of the cerebral cortex is involved with vision. Functional magnetic resonance imaging (fMRI) has made it possible to establish homologies between the visual areas of the macaque and human brains (Figure 25–7). Based on pathway tracing studies in monkeys, we now appreciate that these areas are organized in functional streams (Figure 25–7B).

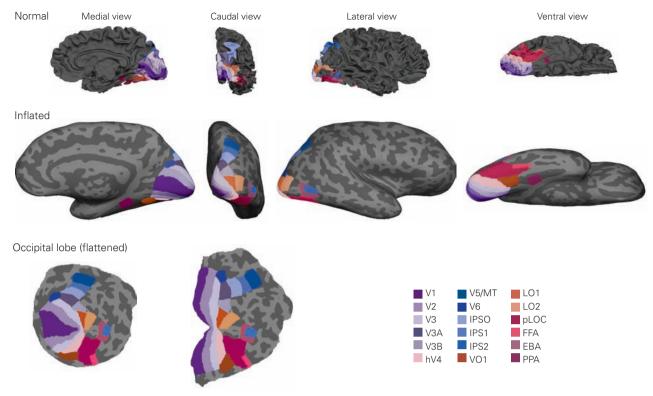

The visual areas of cortex can be differentiated either by their representation of visual space, known as a visuotopic (or retinotopic) map, or by the functional properties of their neurons. Studies of these two differences have revealed that the visual areas are organized in two hierarchical pathways, a ventral pathway involved in object recognition and a dorsal pathway dedicated to the use of visual information for guiding movements. The ventral or object-recognition pathway extends from the primary visual cortex to the temporal lobe; it is described in detail in Chapter 28. The dorsal

Figure 25–6 Pathways for visual processing, pupillary reflex and accommodation, and control of eye position.

A. Visual processing. The eye sends information first to thalamic nuclei, including the lateral geniculate nucleus and pulvinar, and from there to cortical areas. Cortical projections go forward from the primary visual cortex to areas in the parietal lobe (the dorsal pathway, which is concerned with visually guided movement) and areas in the temporal lobe (the ventral pathway, which is concerned with object recognition). The pulvinar also serves as a relay between cortical areas to supplement their direct connections.

- B. Pupillary reflex and accommodation. Light signals are relayed through the midbrain pretectum, to preganglionic parasympathetic neurons in the Edinger-Westphal nucleus, and out through the parasympathetic outflow of the oculomotor nerve to the ciliary ganglion. Postganglionic neurons innervate the smooth muscle of the pupillary sphincter, as well as the muscles controlling the lens.
- C. Eye movement. Information from the retina is sent to the superior colliculus (SC) directly along the optic nerve and indirectly through the geniculostriate pathway to cortical areas (primary visual cortex, posterior parietal cortex, and frontal eye fields) that project back to the superior colliculus. The colliculus projects to the pons (PPRF), which then sends control signals to oculomotor nuclei, including the abducens nucleus, which controls lateral movement of the eyes. (FEF, frontal eye field; LGN, lateral geniculate nucleus; PPRF, paramedian pontine reticular formation.)

A Cortical visual areas in humans

B Visual pathways in the macaque monkey

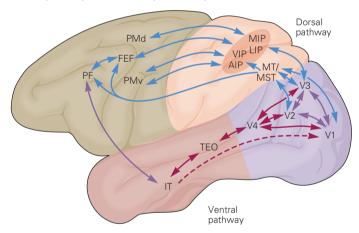

Figure 25-7 Visual pathways in the cerebral cortex.

A. Areas of the human cerebral cortex involved in visual processing as shown by fMRI. The top row shows areas on the gyri and sulci of a normal brain; the middle row shows inflated views of the brain, with light and dark grey regions representing gyri and sulci; the bottom row shows a two-dimensional representation of the occipital lobe (left) and a representation with less distortion by making a cut along the calcarine fissure. The areas are delineated by stimulus-based retinotopy (early visual areas V1, V2, and V3 converge at the representation of the fovea at the occipital pole, V3A, V3B, V6, V7, hV4, VO1, LO1, LO2, V5/MT), attention-based retinotopy (IPS1 and IPS2), or responsiveness to specific attributes or classes of objects (for less strictly retinotopic areas). Functional specificity has been demonstrated for a number of these areas: VO1 is implicated in color processing, the lateral occipital complex (LO2, pLOC) codes object shape, FFA (fusiform face area) codes faces, the parahippocampal place area (PPA) responds more strongly to places than to objects, the extrastriate body area (EBA) responds more strongly to body

parts than objects, and V5/MT is involved in motion processing. Areas in the intraparietal sulcus (IPS1 and IPS2) are involved in control of spatial attention and saccadic eye movements. (Images from V. Piech, reproduced with permission.)

B. In the macaque monkey V1 is located on the surface of the occipital lobe and sends axons in two pathways. A dorsal pathway courses through a number of areas in the parietal lobe and into the frontal lobe, and a ventral pathway projects through V4 into areas of the inferior temporal cortex. In addition to feedforward pathways extending from primary visual cortex into the temporal, parietal, and frontal lobes, there are reciprocal or feedback pathways running in the opposite direction. (AIP, anterior intraparietal area; FEF, frontal eye field; IT, inferior temporal cortex; LIP, lateral intraparietal area; MIP, medial intraparietal area; MT, middle temporal area; PF, prefrontal cortex; PMd, dorsal premotor cortex; PMv, ventral premotor cortex; V1, primary visual cortex, Brodmann's area 17; V2, secondary visual area, Brodmann's area 18; V3, V4, third and fourth visual areas; VIP, ventral intraparietal area.)

or movement-guidance pathway connects the primary visual cortex with the parietal lobe and then with the frontal lobes.

The pathways are interconnected so that information is shared. For example, movement information in the dorsal pathway can contribute to object recognition through kinematic cues. Information about movements in space derived from areas in the dorsal pathway is therefore important for the perception of object shape and is fed into the ventral pathway.

Reciprocity is an important feature of the connectivity between cortical areas. All connections between cortical areas are reciprocal—each area sends information back to the areas from which it receives input. These feedback connections provide information about cognitive functions, including spatial attention, stimulus expectation, and emotional content, to earlier levels of visual processing. The pulvinar in the thalamus serves as a relay between cortical areas (see Figure 25–6A).

The dorsal pathway courses through the parietal cortex, a region that uses visual information to direct the movement of the eyes and limbs, that is, for visuomotor integration. One area, the lateral intraparietal area named for its location in the interparietal sulcus, is involved in representing points in space that are the targets of eye movements or reaching. Patients with lesions of parietal areas fail to attend to objects on one side of the body, a syndrome called *unilateral neglect* (see Chapter 17).

The ventral pathway extends into the temporal lobe. The inferior temporal cortex stores information about the shapes and identities of objects; one portion represents faces, for damage to that region results in the inability to recognize faces (*prosopagnosia*).

The dorsal and ventral pathways each comprise a hierarchical series of areas that can be delineated by several criteria. First, at many relays the array of inputs forms a map of the visual hemifield, and each such representation can be used to delineate a visual area. This is particularly useful at early levels of the pathway where the receptive fields of neurons are small and visuotopic maps are precisely organized. At higher levels, however, the receptive fields become larger, the maps less precise, and visuotopic organization is therefore a less reliable basis to delineate the boundaries of an area.

Another means to differentiate one area from another, as shown by experiments in monkeys, depends upon the distinctive functional properties exhibited by the neurons in each area. The clearest example of this is an area in the dorsal pathway, the middle temporal area (MT or V5), which contains neurons with a strong selectivity for the direction of movement across their

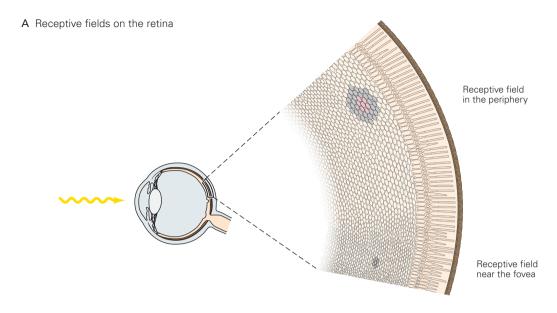

receptive fields. Consistent with the idea that the middle temporal area is involved in the analysis of motion, lesions of this area produce deficits in the ability to track moving objects.

The Receptive Fields of Neurons at Successive Relays in an Afferent Pathway Provide Clues to How the Brain Analyzes Visual Form

In 1906 Charles Sherrington coined the term *receptive field* in his analysis of the scratch withdrawal reflex: "The whole collection of points of skin surface from which the scratch-reflex can be elicited is termed the receptive field of that reflex." When it became possible to record from single neurons in the eye, H. Keffer Hartline applied the concept of the receptive field in his study of the retina of the horseshoe crab, *Limulus*: "The region of the retina which must be illuminated in order to obtain a response in any given fiber . . . is termed the receptive field of that fiber." In the visual system a neuron's receptive field represents a small window on visual space (Figure 25–8).

But responses measured with only one spot of light yielded only a limited understanding of a cell's receptive field. Using two small spots of light, both Hartline and Stephen Kuffler, who studied the mammalian retina, found an inhibitory surround or lateral inhibitory region in the receptive field. In 1953 Kuffler observed that "not only the areas from which responses can actually be set up by retinal illumination may be included in a definition of the receptive field but also all areas which show a functional connection, by an inhibitory or excitatory effect on a ganglion cell." Kuffler thus revealed that the receptive fields of retinal ganglion cells have functionally distinct subareas. These receptive fields have a center-surround organization and fall into one of two categories: on-center and off-center. Later work demonstrated that neurons in the lateral geniculate nucleus have similar receptive fields.

The on-center cells fire when a spot of light is turned on within a circular central region. Off-center cells fire when a spot of light in the center of their receptive field is turned off. The surrounding annular region has the opposite sign. For on-center cells a light stimulus that does not include the center produces a response when the light is turned off, a response termed *on-center*, *off-surround*. The center and surround areas are mutually inhibitory (Figure 25–9). When both center and surround are illuminated with diffuse light there is little or no response. Conversely, a light-dark boundary across the receptive field produces a brisk response. Because these neurons are most sensitive to

B Receptive field of a retinal ganglion cell

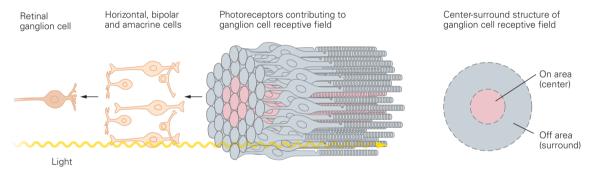

Figure 25–8 Receptive fields of retinal ganglion cells in relation to photoreceptors.

A. The number of photoreceptors contributing to the receptive field of a retinal ganglion cell varies depending on location on the retina. A cell near the fovea receives input from fewer receptors covering a smaller area, whereas a cell farther from

the fovea receives input from many more receptors covering a larger area (see Figure 25–10).

B. Light passes through nerve cell layers to reach the photoreceptors at the back of the retina. Signals from the photoreceptors are then transmitted through neurons in the outer and inner nuclear layers to a retinal ganglion cell.

borders and contours—to differences in illumination as opposed to uniform surfaces—they encode information about contrast in the visual field.

The size on the retina of a receptive field varies both according to the field's *eccentricity*—its position relative to the fovea, the central part of the retina where visual acuity is highest—and the position of neurons along the visual pathway. Receptive fields with the same eccentricity are relatively small at early levels in visual processing and become progressively larger at later levels. The size of the receptive field is expressed in terms of degrees of visual angle; the entire visual field covers nearly 180° (Figure 25–10A). In early

relays of visual processing the receptive fields near the fovea are the smallest. The receptive fields for retinal ganglion cells that monitor portions of the fovea subtend approximately 0.1°, whereas those in the visual periphery reach up to 10°.

The amount of cortex dedicated to a degree of visual space changes with eccentricity. More cortical space is dedicated to the central part of vision, where the receptive fields are smallest and the visual system has the greatest spatial resolution (Figure 25–10C).

Receptive-field properties change from relay to relay along a visual pathway. By determining these properties one can assay the function of each relay

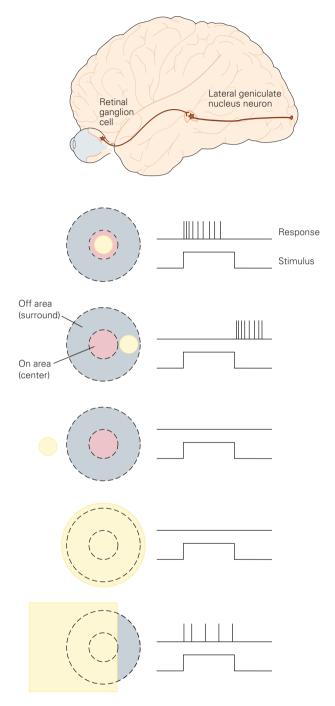

Figure 25–9 Receptive fields of neurons at early relays of visual pathways. A circular symmetric receptive field with mutually antagonistic center and surround is characteristic of retinal ganglion cells and neurons in the lateral geniculate nucleus of the thalamus. The center can respond to the onset or offset of a spot of light (yellow), and the surround has the opposite response. Outside the surround there is no response, thus defining the receptive field boundary. The response is weak when light covers both the center and surround, so these neurons respond optimally to contrast (a light-dark boundary) in the visual field.

nucleus and how visual information is progressively analyzed by the brain. For example, the change in receptive-field structure that occurs between the lateral geniculate nucleus and cerebral cortex reveals an important mechanism in the brain's analysis of visual form. The key property of the form pathway is selectivity for the orientation of contours in the visual field. This is an emergent property of signal processing in primary visual cortex; it is not a property of the cortical input but is generated within the cortex itself.

Whereas retinal ganglion cells and neurons in the lateral geniculate nucleus have concentric centersurround receptive fields, those in the cortex, although equally sensitive to contrast, also analyze contours. David Hubel and Torsten Wiesel discovered this characteristic in 1958 while studying what visual stimuli provoked activity in neurons in the primary visual cortex. While showing an anesthetized animal slides containing a variety of images, they recorded extracellularly from individual neurons in the visual cortex. As they switched from one slide to another they found a neuron that produced a brisk train of action potentials. The cell was responding not to the image on the slide but to the edge of the slide as it was moved into position.

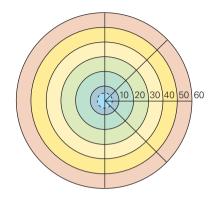

The Visual Cortex Is Organized into Columns of Specialized Neurons

The dominant feature of the functional organization of the primary visual cortex is the visuotopic organization of its cells: the visual field is systematically represented across the surface of the cortex (Figure 25–11A).

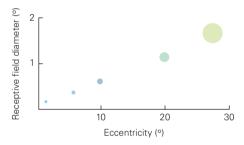

In addition, cells in the primary visual cortex with similar functional properties are located close together in columns that extend from the cortical surface to the white matter. The columns are concerned with the functional properties that are analyzed in any given cortical area and thus reflect the functional role of that area in vision. The properties that are developed in the primary visual cortex include orientation specificity and the integration of inputs from the two eyes, which is measured as the relative strength of input from each eye, or ocular dominance.

Ocular-dominance columns reflect the segregation of thalamocortical inputs arriving from different layers of the lateral geniculate nucleus. Alternating layers of this nucleus receive input from retinal ganglion cells located in either the ipsilateral or contralateral retina (Figure 25–12). This segregation is maintained in the inputs from the lateral geniculate nucleus to the primary visual cortex, producing the alternating left-eye and right-eye ocular dominance bands (Figure 25–11B),

A Map of retinal eccentricity

B Receptive field size varies systematically with eccentricity

C Cortical magnification varies with eccentricity

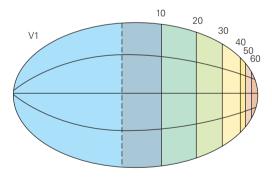

Figure 25–10 Receptive field size, eccentricity, retinotopic organization, and magnification factor. The color code refers to position in visual space or on the retina.

A. The distance of a receptive field from the fovea is referred to as the eccentricity of the receptive field.

- **B.** Receptive field size varies with distance from the fovea. The smallest fields lie in the center of gaze, the fovea, where the visual resolution is highest; fields become progressively larger with distance from the fovea.
- C. The amount of cortical area dedicated to inputs from within each degree of visual space, known as the magnification factor, also varies with eccentricity. The central part of the visual field commands the largest area of cortex. For example, in area V1 more area is dedicated to the central 10° of visual space than to all the rest. The map of V1 shows the cortical sheet unfolded.

which receive input from the respective layers of the lateral geniculate nucleus.

Cells with similar orientation preferences are also grouped into columns. Across the cortical surface there is a regular clockwise and counterclockwise cycling of orientation preference with the full 180° cycle repeating every 750 μ m (Figure 25–11C). One full cycle of orientation columns is called a *hypercolumn*. Likewise, the left- and right-eye dominance columns alternate with a periodicity of 750 to 1,000 μ m. The orientation and ocular dominance columns are crisscrossed over the cortical surface.

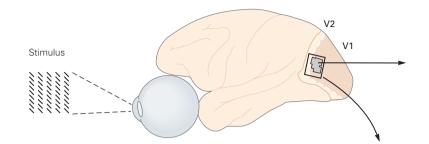

Both types of columns were first mapped by recording the responses of neurons at closely spaced electrode penetrations in the cortex. The ocular-dominance columns were also identified by making lesions or tracer injections in individual layers of the lateral geniculate nucleus. More recently a technique known as optical imaging has enabled researchers to visualize a surface representation of the orientation and ocular dominance columns in living animals. Developed for studies of cortical organization by Amiram Grinvald, this technique visualizes changes in surface reflectance associated with the metabolic requirements of active groups of neurons, known as intrinsic-signal optical imaging, or changes in fluorescence of voltage-sensitive dyes. Intrinsic-signal imaging depends on activity-associated changes in local blood flow and alterations in the oxidative state of hemoglobin and other intrinsic chromophores.

An experimenter can visualize the distribution of cells with left or right ocular dominance, for example, by subtracting the image obtained while stimulating one eye from that acquired while stimulating the other. When viewed in a plane tangential to the cortical surface, the ocular dominance columns appear as alternating left- and right-eye stripes, each approximately 750 µm in width (Figure 25–11B).

The cycles of orientation columns form various structures, from parallel stripes to pinwheels. Sharp jumps in orientation preference occur at the pinwheel centers and "fractures" in the orientation map (Figure 25–11C). Superimposed on these is a third columnar system of continuously changing directional preference.

Embedded within the orientation and oculardominance columns are clusters of neurons that have poor orientation selectivity but strong color preferences. These units of specialization, located within the superficial layers, were revealed by a histochemical label for the enzyme cytochrome oxidase, which is distributed in a regular patchy pattern of blobs and interblobs. In the primary visual cortex these blobs are

D Blobs, interblobs (V1), and stripes (V2)

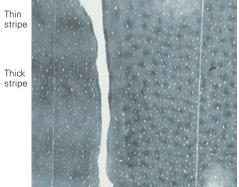

Figure 25–11 (Opposite) Functional architecture of the primary visual cortex. (Images from M. Kinoshita and A. Das, reproduced with permission.)

A. The surface of the primary visual cortex is functionally organized in a map of the visual field. The elevations and azimuths of visual space are organized in a regular grid that is distorted because of variation in the magnification factor (see Figure 25–10). The grid is visible here in the dark stripes (visualized with intrinsic-signal optical imaging), which reflect the pattern of neurons that responded to a series of vertical candy stripes. Within this surface map one finds repeated superimposed cycles of functionally specific columns of cells, as illustrated in B, C, and D.

B. The dark and light stripes represent the surface view of the left and right ocular dominance columns. These stripes intersect the border between areas V1 and V2, the representation of the vertical meridian, at right angles.

C. Some columns contain cells with similar selectivity for the orientation of stimuli. The different colors indicate the orientation preference of the columns. The orientation columns in surface view are best described as pinwheels surrounding singularities of sudden changes in orientation (the center of the pinwheel). The scale bar represents 1 mm. (Surface image of orientation columns on the left reproduced, with permission, from G. Blasdel.)

D. Patterns of blobs in V1 and stripes in V2 represent other modules of functional organization. These patterns are visualized with cytochrome oxidase.

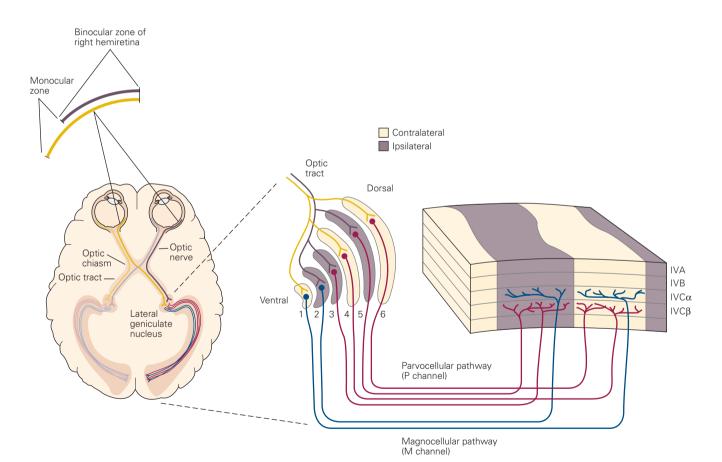

Figure 25–12 Projections from the lateral geniculate nucleus to the visual cortex. The lateral geniculate nucleus in each hemisphere receives input from the temporal retina of the ipsilateral eye and the nasal retina of the contralateral eye. The nucleus is a laminated structure comprising four parvocellular layers (layers 3 to 6) and two magnocellular layers (layers 1 and 2). The inputs from the two eyes terminate in different layers: The contralateral eye projects to layers 1, 4, and 6, whereas

the ipsilateral eye sends input to layers 2, 3, and 5. The parvocellular and magnocellular inputs to the primary visual cortex arrive in separate sublayers. The parvocellular layers project to layer IVC β and the magnocellular layers to layer IVC α . In addition, the afferents from the ipsilateral and contralateral layers of the lateral geniculate nucleus are segregated into alternating ocular-dominance columns.

a few hundred micrometers in diameter and 750 μ m apart (Figure 25–11D). The blobs correspond to clusters of color-selective neurons. Because they are rich in cells with color selectivity and poor in cells with orientation selectivity, the blobs are specialized to provide information about surfaces rather than edges.

In area V2 thick and thin dark stripes separated by pale stripes are evident with cytochrome oxidase labeling (Figure 25–11D). The thick stripes contain neurons selective for direction of movement and for binocular disparity as well as cells that are responsive to illusory contours and global disparity cues. The thin stripes hold cells specialized for color. The pale stripes contain orientation-selective neurons.

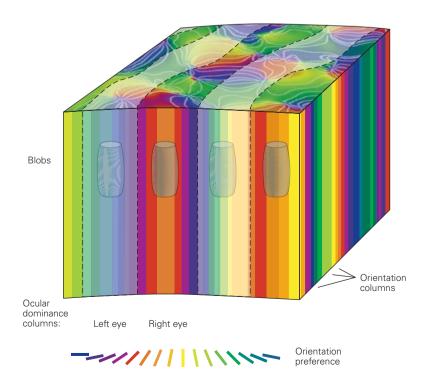

For every visual attribute to be analyzed at each position in the visual field there must be adequate tiling, or coverage, of neurons with different functional properties. As one moves in any direction across the cortical surface, the progression of the visuotopic location of receptive fields is gradual, whereas the cycling of columns occurs more rapidly. Any given position in space can therefore be analyzed adequately in terms of the orientation of contours, the color and direction of movement of objects, and the stereoscopic depth. The small segment of visual cortex that deals with that particular part of the visual field represents all possible values of all the columnar systems (Figure 25–13).

The columnar systems serve as the substrate for two fundamental types of connectivity along the visual pathway. *Serial processing* occurs in the successive connections between cortical areas, connections that run from the back of the brain forward. At the same time *parallel processing* occurs simultaneously in subsets of fibers that process different submodalities such as form, color, and movement.

Many areas of visual cortex reflect this arrangement; for example, functionally specific cells in V1 communicate with cells of the same specificity in V2. These pathways are not absolutely segregated, however, for there is some mixing of information between different visual attributes (Figure 25–14).

Columnar organization confers several advantages. It minimizes the distance required for neurons with similar functional properties to communicate with one another and allows them to share inputs from discrete pathways that convey information about particular sensory attributes. This efficient connectivity economizes on the use of brain volume and maximizes processing speed. The clustering of neurons into functional groups, as in the columns of the cortex, allows the brain to minimize the number of neurons required for analyzing different attributes. If all neurons were tuned for every attribute, the resultant combinatorial explosion would require a prohibitive number of neurons.

Figure 25–13 A cortical computational module. A chunk of cortical tissue roughly 1 mm in diameter contains an orientation hypercolumn (a full cycle of orientation columns), one cycle of left- and right-eye ocular-dominance columns, and blobs and interblobs. This module would presumably contain all of the functional and anatomical cell types of primary visual cortex, and would be repeated hundreds of times to cover the visual field. (Adapted, with permission, from Hubel 1988.)

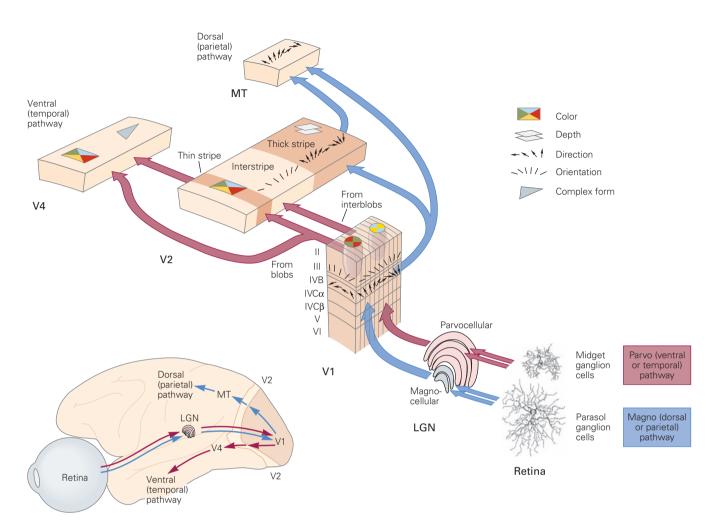

Figure 25–14 Parallel processing in visual pathways. The ventral stream is primarily concerned with object identification, carrying information about form and color. The dorsal pathway is dedicated to visually guided movement, with cells selective for direction of movement. These pathways are not strictly

segregated, however, and there is substantial interconnection between them even in the primary visual cortex. (LGN, lateral geniculate nucleus; MT, middle temporal area.) (Retinal ganglion cell images from Dennis Dacey, reproduced with permission.)

Intrinsic Cortical Circuits Transform Neural Information

Each area of the visual cortex transforms information gathered by the eyes and processed at earlier synaptic relays into a signal that represents the visual scene. This transformation is accomplished by local circuits formed by excitatory and inhibitory neurons.

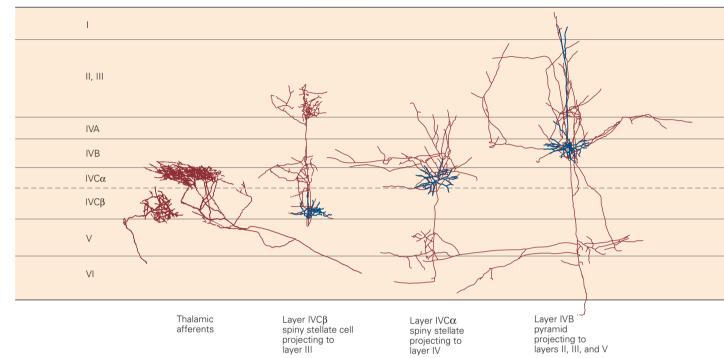

The principal input to the primary visual cortex comes from two parallel pathways that originate in the parvocellular and magnocellular layers of the lateral geniculate nucleus (see Figure 25–12). Neurons in the parvocellular layers project to cortical layer IVC β , whereas those in the magnocellular layers project to

layer IVCα. From there a sequence of interlaminar connections, mediated by the excitatory spiny stellate neurons, processes visual information over a stereotyped set of connections (Figure 25–15).

This characterization of parallel pathways is only an approximation, as there is considerable interaction between the pathways. This interaction is the means by which various visual features—color, form, depth, and movement—are linked, leading to a unified visual percept. One way this linkage, or binding, may be accomplished is through cells that are tuned to more than one attribute.

At each stage of cortical processing pyramidal neurons extend output to other brain areas. Superficial-layer

B Simplified diagram of intrinsic circuitry

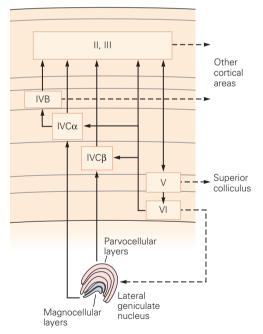

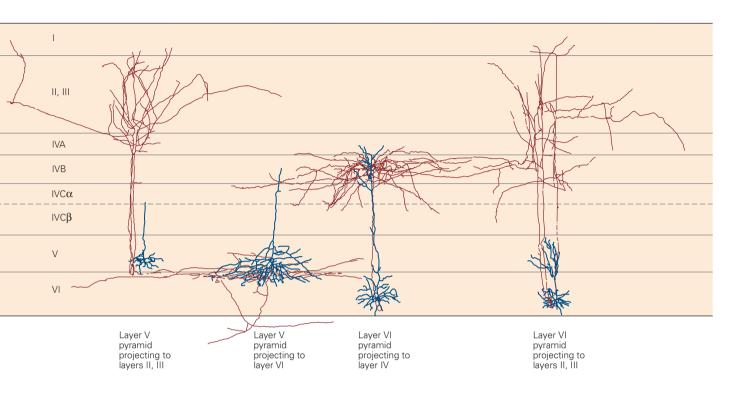

Figure 25–15 The intrinsic circuitry of the primary visual cortex.

A. Examples of neurons in different cortical layers responsible for excitatory connections in cortical circuit. Layer IV is the principal layer of input from the lateral geniculate nucleus of the thalamus. Fibers from the parvocellular layer terminate in layer IVC β , while the magnocellular fibers terminate in layer IVC α . The intrinsic cortical excitatory connections are mediated by spiny stellate and pyramidal cells. A variety of γ -aminobutyric acid (GABA)-ergic smooth stellate cells (not shown) are responsible for inhibitory connections. Dendritic arbors are colored blue, and axonal arbors are shown in brown. (Cortical neurons reproduced, with permission, from E. Callaway.)

B. Schematic diagram of excitatory connections within the primary visual cortex. Output to other regions of cortex is sent from every layer of visual cortex. (Thalamic afferents adapted, with permission, from Blasdel and Lund 1983.)

cells are responsible for connections to higher-order areas of cortex. Layer V pyramidal neurons project to the superior colliculus and pons in the brain stem. Layer VI cells are responsible for feedback projections, both to the thalamus and to lower-order cortical areas.

Neurons in different layers have distinctive receptive-field properties. Neurons in the superficial layer of V1 have small receptive fields whereas deeperlayer neurons have large ones. The superficial-layer neurons are specialized for high-resolution pattern

recognition. The deeper-layer neurons, such as those in layer V that are selective for the direction of movement, are specialized for the tracking of objects in space.

Feedback projections are thought to provide a means whereby higher centers in a pathway can influence lower ones. The number of neurons projecting from the cortex to the lateral geniculate nucleus is tenfold the number providing input to the cortex from the lateral geniculate nucleus. Although this feedback projection is obviously important, its function is largely unknown.

In addition to serial feed-forward and feedback connections, an important component of cortical circuits are the fibers that travel parallel to the cortical surface within each layer and provide long-range horizontal connections (Figure 25–16). These connections and their role in the functional architecture of cortex were analyzed by Charles Gilbert and Torsten Wiesel, who used intracellular recordings and dye injection to correlate anatomical features with cortical function. Because the visual cortex is organized visuotopically, the horizontal connections allow target neurons to integrate information over a relatively large area of the visual field and are therefore important in assembling the components of a visual image into a unified percept.

Integration can also be achieved by other means. The considerable convergence and divergence of connections at the synaptic relays of the afferent visual pathway imply that the receptive fields of neurons are larger and more complex at each successive relay and thus necessarily acquire an integrative function. Feedback connections may also support integration, both because of their divergence and because they originate from cells with larger receptive fields.

Visual Information Is Represented by a Variety of Neural Codes

Individual neurons in a sensory pathway respond to a range of stimulus values. For example, a neuron in a color-detection pathway is not limited to responding to one wavelength but is instead tuned to a range of wavelengths. A neuron's response peaks at a particular value and tails off on either side of that value, forming a bell-shaped tuning curve with a particular bandwidth. Thus a neuron with a peak response at 650 nm and a bandwidth of 100 nm might give identical responses at 600 nm and 700 nm.

To be able to determine the wavelength from neuronal signals one needs at least two neurons representing

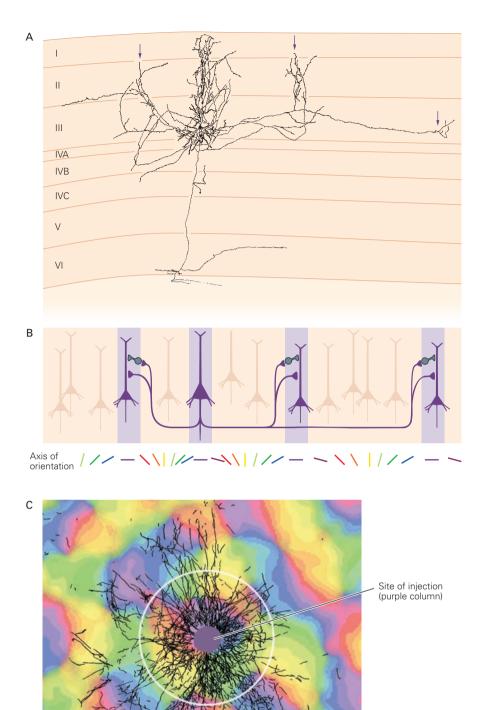

Figure 25–16 Long-range horizontal connections in each layer of the visual cortex integrate information from different parts of the visual field.

A. The axons of pyramidal cells extend for many millimeters parallel to the cortical surface. Axon collaterals form connections with other pyramidal cells as well as with inhibitory interneurons. This arrangement enables neurons to integrate information over large parts of the visual field. An important characteristic of these connections is their relationship to the functional columns. The axon collaterals are found in clusters (arrows) at distances greater than 0.5 mm from the cell

body. (Reproduced, with permission, from Gilbert and Wiesel 1983.)

B. Horizontal connections link columns of cells with similar orientation specificity.

Connections with columns of similar orientation

C. The pattern of horizontal connections is visualized by injecting an adenoviral vector containing the gene encoding green fluorescent protein into one orientation column and superimposing the labeled image (black) on an optically imaged map of the orientation columns in the vicinity of the injection. (Scale: diameter of white circle is 1 mm.) (Reproduced, with permission, from Stettler et al. 2002.)

filters centered at different wavelengths. Each neuron can be thought of as a *labeled line* in which activity signals a stimulus with a given value. When more than one such neuron fires, the convergent signals at the postsynaptic relay represent a stimulus with a wavelength that is the weighted average of the values represented by all the inputs.

A single visual percept is the product of the activity of a number of neurons operating in a specific combinatorial and interactive fashion called a *population code*. Population coding has been modeled in various ways. The most prevalent model is called *vector averaging*.

We can illustrate population coding with a population of orientation-selective cells, each of which responds optimally to a line with a specific orientation. Each neuron responds not just to the preferred stimulus but rather to any line that falls within a range of orientations described by a Gaussian tuning curve with a particular bandwidth. A stimulus of a particular orientation most strongly activates cells with tuning curves centered at that orientation; cells with tuning curves centered away from but overlapping that orientation are excited less strongly.

Each cell's preferred orientation, the line label, is represented as a vector pointing in the direction of that orientation. Each cell's firing is a "vote" for the cell's line label, and the cell's firing rate represents the weighting of the vote. The cell's signal can thus be represented by a vector pointing in the direction of the cell's preferred orientation with a length proportional to the strength of the cell's response. For all the activated cells one can calculate a vector sum with a direction that represents the value of the stimulus (Figure 25–17).

Another aspect of the population code is the variability of a neuron's response to the same stimulus. Repeated presentations of the same stimulus to a neuron sensitive to that stimulus will elicit a range of responses. The most sensitive part of a neuron's tuning curve lies not at the peak but along the flanks, where the tuning curve is steepest. Here small changes in the value of a stimulus produce the strongest change in response. Changes in stimulus value must, however, be sufficient to elicit a change in response that significantly exceeds the normal variability in the response of the neuron. One can compare that amount of change to the perceptual discrimination threshold. When many neurons contribute to the discrimination, the signal-to-noise ratio increases, a process known as probability summation, and the critical difference in stimulus value required for a significant change in neuronal response is less.

When the brain represents a piece of information, an important consideration is the number of neurons that participate in that representation. Although all information about a visual stimulus is present in the retina,

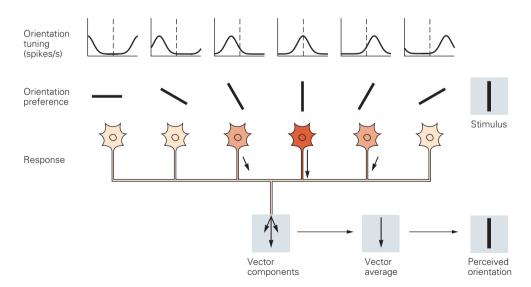

Figure 25–17 Vector averaging is one model for population coding in neural circuits. Vector averages describe the possible relationship between the responses in an ensemble of neurons, the tuning characteristics of individual neurons in the ensemble, and the resultant percept. Individual neurons respond optimally to a particular orientation of a stimulus in the visual field, but also respond at varying rates to a range of orientations. The stimulus orientation to which a neuron fires

best can be thought of as a line label—when the cell fires briskly, its activity signifies the presence of a stimulus with that orientation. A number of neurons with different orientation preferences will respond to the same stimulus. Each neuron's response can be represented as a vector whose length indicates the strength of its response and whose direction represents its preferred orientation, or line label. (Adapted, with permission, from Kapadia, Westheimer, and Gilbert 2000.)

the retinal representation is not sufficient for object recognition. At the other end of the visual pathway some neurons in the temporal lobe are selective for complex objects, such as faces. Can an individual cell represent something as complex as a particular face? Such a hypothetical neuron has been dubbed a "grandmother cell" because it would represent exclusively a person's grandmother, or a "pontifical cell" because it would represent the apex of a hierarchical cognitive pathway.

The nervous system does not, however, represent entire objects by the activity of single neurons. Instead some cells represent parts of an object and an ensemble of neurons represents an entire object. Each member of the ensemble may participate in different ensembles that are activated by different objects. This arrangement is known as a *distributed code*. Distributed codes can involve a few neurons or many. In any case, a distributed code requires complex connectivity between the cells representing a face and those representing the name and experiences associated with that person.

The foregoing discussion assumes that neurons signal information by their firing rate and their line labels. An alternative hypothesis is that the timing of action potentials itself carries information in a kind of Morse code. The code might be read from the synchronous firing of different sets of neurons over time. At one instant one group of cells might fire together followed by the synchronous firing of another group. Over a single train of action potentials a single cell could participate in many such ensembles. Whether sensory information is represented this way, and whether the nervous system carries more information than that represented by firing rate alone, is not known.

An Overall View

Visual perception involves an interaction between the retina, thalamic nuclei, and multiple areas of the cerebral cortex. The retina defines the limits of vision: the ability to resolve fine details, the discrimination of tiny movements, and the capacity to detect subtle contrasts and differences in the wavelength of reflected light.

The visual cortex acquires information coming from complex scenes, parses it into the surfaces and contours belonging to individual objects, and segments those objects from their background. This process involves a simultaneous analysis of local properties, such as orientation, direction of movement, and color, as well as the integration of these properties across space.

The mechanisms of visual processing may be observed in the receptive-field properties of individual neurons and in the functional organization of the cortex. Certain aspects of vision are analyzed in

parallel by distinct pathways, one of which is involved in object recognition and another in visually guided movements.

An Overall View

All visual experience is based on information processed by this neural circuit in the eye. The retina's output is conveyed to the brain by just one million optic nerve fibers, and yet almost half of the cerebral cortex is used to process these signals. Visual information lost in the retina—by design or deficiency—can never be recovered. Because retinal processing sets fundamental limits on what can be seen, there is great interest in understanding how the retina functions.

On the surface the vertebrate eye appears to act much like a camera. The pupil forms a variable diaphragm, and the cornea and lens provide the refractive optics that project a small image of the outside world onto the light-sensitive retina lining the back of the eyeball (Figure 26–1). But this is where the analogy ends. The retina is a thin sheet of neurons, a few hundred micrometers thick, composed of five major cell types that are arranged in three cellular layers separated by two synaptic layers (Figure 26–2).

The photoreceptor cells, in the outermost layer, absorb light and convert it into a neural signal, an essential process known as phototransduction.

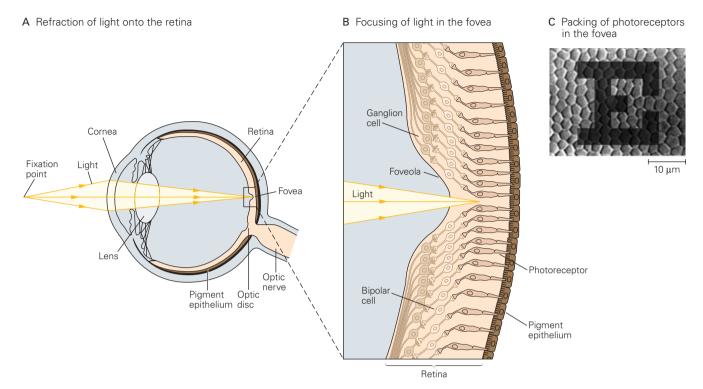

Figure 26–1 The eye projects the visual scene onto the retina's photoreceptors.

A. Light from an object in the visual field is refracted by the cornea and lens and focused onto the retina.

B. In the foveola, corresponding to the very center of gaze, the proximal neurons of the retina are shifted aside so light has direct access to the photoreceptors.

C. A letter from the eye chart for normal visual acuity is projected onto the densely packed photoreceptors in the fovea. Although less sharply focused than shown here as a result of diffraction by the eye's optics, the smallest discernible strokes of the letter are approximately one cone diameter in width. (Adapted, with permission, from Curcio and Hendrickson 1982.)

These signals are passed synaptically to bipolar cells, which in turn connect to retinal ganglion cells in the innermost layer. Retinal ganglion cells are the output neurons of the retina and their axons form the optic nerve. In addition to this vertical pathway from sensory to output neurons, the retinal circuit includes many lateral connections provided by horizontal cells in the outer synaptic layer and amacrine cells in the inner synaptic layer (Figure 26–3).

The retinal circuit performs low-level visual processing, the initial stage in the analysis of visual images. It extracts from the raw images in the left and right eyes certain spatial and temporal features and conveys them to higher visual centers. The rules of this processing are very plastic. In particular, the retina must adjust its sensitivity to ever-changing conditions of illumination. This adaptation allows our vision to remain more or less stable despite the vast range of light intensities encountered during the course of each day.

In this chapter we discuss in turn the three important aspects of retinal function: phototransduction, preprocessing, and adaptation. We will illustrate both the neural mechanisms by which they are achieved and their consequences for visual perception.

The Photoreceptor Layer Samples the Visual Image

Ocular Optics Limit the Quality of the Retinal Image

The sharpness of the retinal image is determined by several factors: diffraction at the pupil's aperture, refractive errors in the cornea and lens, and scattering due to material in the light path. A point in the outside world is generally focused into a small blurred circle on the retina. As in other optical devices this blur is smallest near the optical axis, where the image

quality approaches the limit imposed by diffraction at the pupil. Away from the axis the image is degraded significantly owing to aberrations in the cornea and lens. The image may be degraded further by abnormal conditions such as light-scattering cataracts or refractive errors such as myopia.

The area of retina near the optical axis, the *fovea*, is where vision is sharpest and corresponds to the center of gaze that we direct toward the objects of our attention. The density of photoreceptors, bipolar cells, and ganglion cells is highest at the fovea. The spacing between

photoreceptors there is well matched to the size of the optical blur circle, and thus samples the image in an ideal fashion. Light must generally traverse several layers of cells before reaching the photoreceptors, but in the center of the fovea, called the *foveola*, the other cellular layers are pushed aside to reduce additional blur from light scattering (Figure 26–1B). Finally, the back of the eye is lined by a black pigment epithelium that absorbs light and keeps it from scattering back into the eye.

The retina contains another special site, the optic disc, where the axons of retinal ganglion cells converge

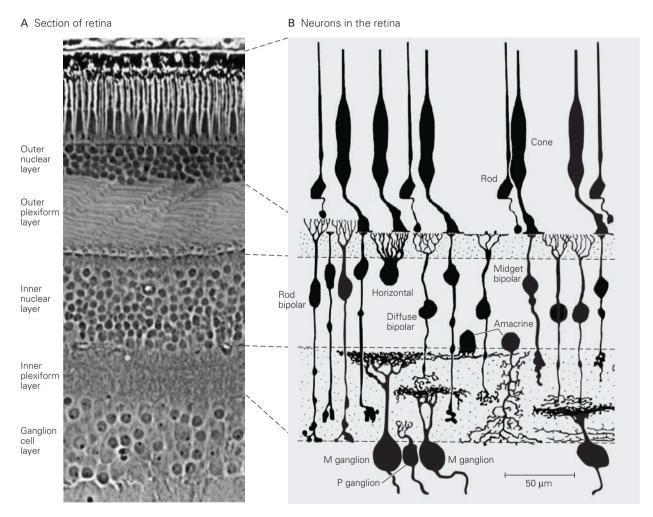

Figure 26–2 The retina comprises five distinct layers of neurons and synapses.

A. A perpendicular section of the human retina seen through the light microscope. Three layers of cell bodies are evident. The outer nuclear layer contains cell bodies of photoreceptors; the inner nuclear layer includes horizontal, bipolar, and amacrine cells; and the ganglion cell layer contains ganglion cells and some displaced amacrine cells. Two layers of fibers and synapses separate these: the outer plexiform layer and the inner plexiform layer. (Reproduced, with permission, from Boycott and Dowling 1969.)

and extend through the retina to emerge from the back of the eye as the optic nerve. By necessity this area is devoid of photoreceptors and thus corresponds to a blind spot in the visual field of each eye. Because the disc lies nasal to the fovea of each eye, light coming from a single point never falls on both blind spots simultaneously, and thus normally we are unaware of them. We can experience the blind spot only by using one eye (Figure 26–4). The blind spot demonstrates what blind people experience—not blackness, but simply nothing. This explains why damage to the peripheral retina often goes unnoticed. It is usually through accidents, such as bumping into an unnoticed object, or through clinical testing that a deficit of sight is revealed.

The blind spot is a necessary consequence of the inside-out design of the retina, which has puzzled and

amused biologists for generations. The purpose of this organization may be to enable the tight apposition of photoreceptors with the retinal pigment epithelium, which plays an essential role in the turnover of retinal pigment and recycles photoreceptor membranes by phagocytosis.

There Are Two Types of Photoreceptors: Rods and Cones

All photoreceptor cells have a common structure with four functional regions: the outer segment, located at the distal surface of the neural retina; the inner segment, located more proximally; the cell body; and the synaptic terminal (Figure 26–5A).

Most vertebrates have two types of photoreceptors, rods and cones, distinguished by their morphology.

Figure 26–4 The blind spot of the human retina. Locate the blind spot in your left eye by shutting the right eye and fixating the cross with the left eye. Hold the book about 12 inches from your eye and move it slightly nearer or farther until the circle on the left disappears. Now place a pencil vertically on the page

and sweep it sideways over the circle. Note the pencil appears unbroken, even though no light can reach your retina from the region of the circle. Next move the pencil lengthwise and observe what happens when its tip enters the circle. (Adapted, with permission, from Hurvich 1981.)

A rod has a long, cylindrical outer segment within which the stacks of discs are separated from the plasma membrane, whereas a cone often has a shorter, tapered outer segment, and the discs are continuous with the outer membrane (Figure 26–5B).

A Morphology of photoreceptors

terminal

Rods and cones also differ in function, most importantly in their sensitivity to light. Rods can signal the absorption of a single photon and are responsible for vision under dim illumination such as moonlight. But as the light level increases toward dawn, the electrical

Outer segment Inner segment Cell body Axon and synaptic

B Outer segment of photoreceptors

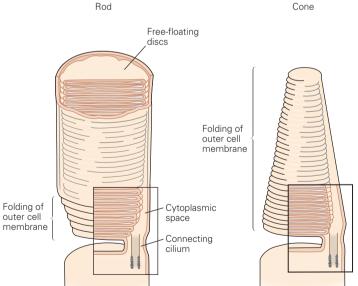

Figure 26–5 Rod and cone photoreceptors have similar structures.

A. Both rod and cone cells have specialized regions called the outer and inner segments. The outer segment, which is attached to the inner segment by a cilium, contains the light-transducing apparatus. The inner segment holds mitochondria and much of the machinery for protein synthesis.

B. The outer segment consists of a stack of membranous discs that contain the light-absorbing photopigments. In both types of cells these discs are formed by infolding of the plasma membrane. In rods, however, the folds pinch off from the membrane so that the discs are free-floating within the outer segment, whereas in cones the discs remain part of the plasma membrane. (Adapted, with permission, from O'Brien 1982; and Young 1970.)

response of rods becomes saturated and the cells cease to respond to variations in intensity. Cones are much less sensitive to light; they make no contribution to night vision, but are solely responsible for vision in daylight. Their response is considerably faster than that of rods. Primates have only one type of rod but three kinds of cone photoreceptors, distinguished by the range of wavelengths to which they respond: the L (long-wave), M (medium-wave), and S (short-wave) cones (Figure 26–6).

The human retina contains approximately 100 million rods and 6 million cones, but the two cell types are differently distributed. The central fovea contains no rods but is densely packed with small cones. A few millimeters outside the fovea rods greatly outnumber cones. All photoreceptors become larger and more widely spaced toward the periphery of the retina. The S cones make up only 10% of all cones and are absent from the central fovea.

The retinal center of gaze is clearly specialized for daytime vision. The dense packing of cone photoreceptors in the fovea sets the limits of our visual acuity. In fact, the smallest letters we can read on a doctor's eye chart have strokes whose images are just 1–2 cone diameters wide on the retina, a visual angle of about

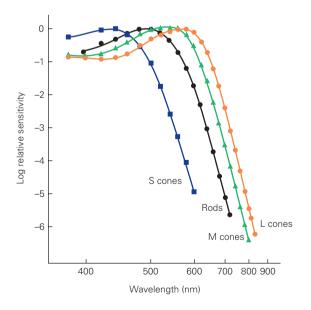

Figure 26–6 Sensitivity spectra for the three cones and the rod. At each wavelength the sensitivity is inversely proportional to the intensity of light required to elicit a criterion neural response. Sensitivity varies over a large range and thus is shown on a logarithmic scale. The different classes of photoreceptors are sensitive to broad and overlapping ranges of wavelengths. (Reproduced, with permission, from Schnapf et al. 1988.)

1 minute of arc (Figure 26–1C). At night the central fovea is blind owing to the absence of rods. Astronomers know that one must look just to the side of a dim star to see it at all. During nighttime walks in the forest we nonastronomers tend to follow our daytime reflex of looking straight at the source of a suspicious sound. Mysteriously, the object disappears, only to jump back into our peripheral field of view as we avert our gaze.

Phototransduction Links the Absorption of a Photon to a Change in Membrane Conductance

As in many other neurons the membrane potential of a photoreceptor is regulated by the balance of membrane conductances to Na⁺ and K⁺ ions, whose transmembrane gradients are maintained by metabolically active pumps (see Chapter 6). In the dark, Na⁺ ions flow into the photoreceptor through nonselective cation channels that are activated by the second messenger cyclic guanosine 3′-5′ monophosphate (cGMP).

Absorption of a photon by the pigment protein sets in motion a biochemical cascade that ultimately lowers the concentration of cGMP, thus closing the cGMP-gated channels and moving the cell closer to the K⁺ equilibrium potential. In this way light hyperpolarizes the photoreceptor (Figure 26–7). Here we describe this sequence of events in detail. Most of this knowledge derives from studies of rods, but the mechanism in cones is very similar.

Light Activates Pigment Molecules in the Photoreceptors

Rhodopsin, the visual pigment in rod cells, has two components. The protein portion, *opsin*, is embedded in the disc membrane and does not by itself absorb visible light. The light-absorbing moiety, *retinal*, is a small molecule whose 11-*cis* isomer is covalently linked to a lysine residue of opsin (Figure 26–8A). Absorption of a photon by retinal causes it to flip from the 11-*cis* to the all-*trans* configuration. This reaction is the only light-dependent step in vision.

The change in shape of the retinal molecule causes a conformational change in the opsin to an activated state called *metarhodopsin II*, which triggers the second step of phototransduction. Metarhodopsin II is unstable and splits within minutes, yielding opsin and free all-*trans* retinal. The all-*trans* retinal is then transported from rods to pigment epithelial cells, where it is reduced to all-*trans* retinol (vitamin A), the precursor of 11-*cis* retinal, which is subsequently transported back to rods.

All-trans retinal is thus a crucial compound in the visual system. Its precursors, such as vitamin A, cannot be synthesized by humans and so must be a regular part of the diet. Deficiencies of vitamin A can lead to night blindness and, if untreated, to deterioration of receptor outer segments and eventually to blindness.

Each type of cone in the human retina produces a variant of the opsin protein. These three cone pigments are distinguished by their *absorption spectrum*, the dependence on wavelength of the efficiency of light absorption (see Figure 26–6). The spectrum is determined by the protein sequence through the interaction between retinal and certain amino-acid side chains near the binding pocket. Red light excites L cones more than the M cones, whereas green light excites the M cones more. Therefore the relative degree of excitation in these cone types contains information about the spectrum of the light, independent of its intensity. The brain's comparison of signals from different cone types is the basis for color vision.

In night vision only the rods are active, so all functional photoreceptors have the same absorption spectrum. A green light consequently has exactly the same effect on the visual system as a red light of a greater intensity. Because a single-photoreceptor system cannot distinguish the spectrum of a light from its intensity, "at night all cats are gray." By comparing the sensitivity of a rod to different wavelengths of light, one obtains the absorption spectrum of rhodopsin. It is a remarkable fact that one can measure this molecular property accurately just by asking human subjects about the appearance of various colored lights (Figure 26–9). The quantitative study of perception, or psychophysics, provides similar insights into other mechanisms of brain processing.

Excited Rhodopsin Activates a Phosphodiesterase Through the G Protein Transducin

Activated rhodopsin, in the form of metarhodopsin II, diffuses within the disc membrane where it encounters transducin, a member of the G protein family (Chapter 11). As is the case for other G proteins, the inactive form of transducin binds a molecule of guanosine diphosphate (GDP). Interaction with metarhodopsin II promotes the exchange of GDP for guanosine triphosphate (GTP). This leads to dissociation of transducin's subunits into an active α subunit carrying the GTP (T α -GTP) and the β and γ subunits (T $\beta\gamma$). Metarhodopsin II can activate hundreds of additional transducin molecules, thus significantly amplifying the cell's response.

The active transducin subunit $T\alpha$ -GTP forms a complex with a cyclic nucleotide phosphodiesterase, another protein associated with the disc membrane. This interaction greatly increases the rate at which the enzyme hydrolyzes cGMP to 5′-GMP. Each phosphodiesterase molecule can hydrolyze more than 1,000 molecules of cGMP per second, thus increasing the degree of amplification.

The concentration of cGMP controls the activity of the cGMP-gated channels in the plasma membrane of the outer segment. In darkness, when the cGMP concentration is high, a sizeable Na⁺ influx through the open channels maintains the cell at a depolarized level of approximately –40 mV. As a consequence, the cell's synaptic terminal continuously releases the transmitter glutamate. The light-evoked decrease in cGMP results in the closure of the cGMP-gated channels, thus reducing the inward flux of Na⁺ ions and hyperpolarizing the cell (Figure 26–7B1). Hyperpolarization slows the release of neurotransmitter from the photoreceptor terminal, thereby initiating a neural signal.

Multiple Mechanisms Shut Off the Cascade

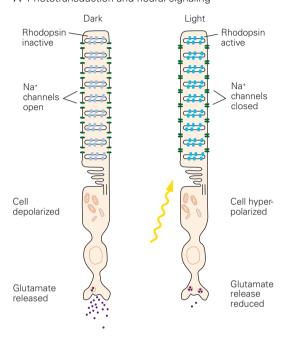

The photoreceptor's response to a single photon must be terminated so that the cell can respond to another photon. Metarhodopsin II is inactivated through phosphorylation by a specific rhodopsin kinase followed by binding of the soluble protein arrestin, which blocks the interaction with transducin.

Active transducin ($T\alpha$ -GTP) has an intrinsic GTPase activity, which eventually converts bound GTP to GDP. $T\alpha$ -GDP then releases phosphodiesterase and recombines with $T\beta\gamma$, ready again for excitation by rhodopsin. Once the phosphodiesterase has been inactivated, the cGMP concentration is restored by a guanylate cyclase that produces cGMP from GTP. At this point the membrane channels open, the Na^+ current resumes, and the photoreceptor depolarizes back to its dark potential.

In addition to these independent mechanisms that shut off individual elements of the cascade, an important feedback mechanism ensures that large responses are terminated more quickly. This is mediated by a change in the Ca²⁺ concentration in the cell. Calcium ions enter the cell through the cGMP-gated channels and are extruded by rapid cation exchangers. In the dark the intracellular Ca²⁺ concentration is high; but during the cell's light response when the cGMP-gated channels close, the Ca²⁺ level drops quickly to a few percent of the dark level.

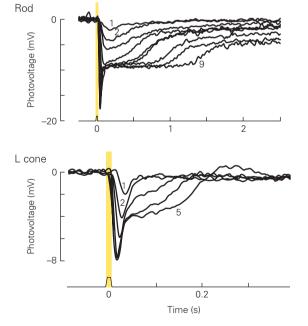

This reduction in Ca²⁺ concentration modulates the biochemical reactions in many ways (Figure 26–7B2).

A Phototransduction and neural signaling

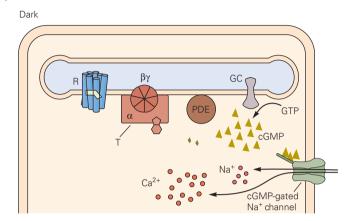

C Voltage response to light

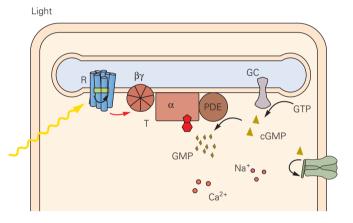

Dark Light

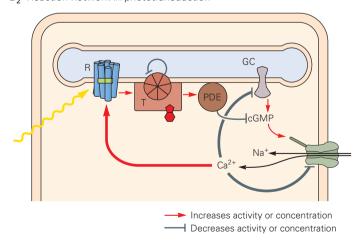

Recovery

B₁ Molecular processes in phototransduction

${\bf B_2}\,$ Reaction network in phototransduction

Rhodopsin phosphorylation is accelerated through the action of the Ca²⁺-binding protein recoverin on rhodopsin kinase, thus reducing activation of transducin. The activity of guanylyl cyclase is accelerated by Ca²⁺-dependent guanylyl cyclase-activating proteins. Finally, the affinity of the cGMP-gated channel is increased through the action of Ca²⁺-calmodulin. All these effects promote the return of the photoreceptor to the dark state.

Defects in Phototransduction Cause Disease

Not surprisingly, defects in the phototransduction machinery have serious consequences. One prominent defect is color blindness, which results from loss or abnormality in the genes for cone pigments, as discussed below.

Stationary night blindness results when rod function has been lost but cone function remains intact. This disease is heritable, and mutations have been identified in many components of the phototransduction cascade: rhodopsin, rod transducin, rod phosphodiesterase, rhodopsin kinase, and arrestin. In some cases it appears that the rods are permanently activated, as if exposed to a constant blinding light.

Unfortunately, many defects in phototransduction lead to *retinitis pigmentosa*, a progressive degeneration of the retina that ultimately results in blindness. The disease has multiple forms, many of which have been associated with mutations that affect signal transduction in rods. Why these changes in function lead to death of the rods and subsequent degeneration of the cones is not understood.

Figure 26-7 (Opposite) Phototransduction.

A. The rod cell responds to light. Rhodopsin molecules in the outer-segment discs absorb photons, which leads to the closure of cGMP-gated channels in the plasma membrane. This channel closure hyperpolarizes the membrane and reduces the rate of release of the neurotransmitter glutamate. (Adapted, with permission, from Alberts 2008.)

B. 1. Cyclic GMP (cyclic guanosine 3'-5' monophosphate) is produced by a guanylate cyclase (GC) and hydrolyzed by a phosphodiesterase (PDE). In the dark the phosphodiesterase activity is low, the cGMP concentration is high, and the cGMP-gated channels are open, allowing the influx of Na⁺ and Ca²⁺. In the light rhodopsin (R) is excited by absorption of a photon, then activates transducin (T), which in turn activates the phosphodiesterase; the cGMP level drops, the membrane channels close, and less Na⁺ and Ca²⁺ enter the cell. The transduction enzymes are all located in the internal membrane discs, and the soluble ligand cGMP serves as a messenger to the plasma membrane.

Ganglion Cells Transmit Neural Images to the Brain

The photoreceptor layer produces a relatively simple neural representation of the visual scene: Neurons in bright regions are hyperpolarized, whereas those in dark regions are depolarized. Because the optic nerve has only about 1% as many axons as there are receptor cells, the retinal circuit must edit the information in the photoreceptors before it is conveyed to the brain.

This step constitutes *low-level visual processing*, the first stage in deriving visual percepts from the pattern of light falling on the retina. To understand this selective process we must first understand the neural image at the retina's output and how retinal ganglion cells respond to various patterns of light.

The Two Major Types of Ganglion Cells Are ON Cells and OFF Cells

Many retinal ganglion cells fire action potentials spontaneously even in darkness or constant illumination. If the light intensity is suddenly increased, so-called ON cells fire more rapidly. Other ganglion cells, the OFF cells, fire more slowly or cease firing altogether. When the intensity diminishes again, the ON cells fire less and OFF cells fire more. The retinal output thus includes two complementary representations that differ in the polarity of their response to light.

This arrangement serves to communicate rapidly both brightening and dimming in the visual scene. If the retina had only ON cells, a dark object would be

- 2. Calcium ions have a negative feedback role in the reaction cascade in phototransduction. Stimulation of the network by light leads to the closure of the cGMP-gated channels. This causes a drop in the intracellular concentration of Ca²⁺. Because Ca²⁺ modulates the function of at least three components of the cascade—rhodopsin, guanylyl cyclase, and the cGMP-gated channel—the drop in Ca²⁺ counteracts the excitation caused by light.
- C. Voltage response of a primate rod and cone to brief flashes of light of increasing intensity. Higher numbers on the traces indicate greater intensities of illumination (not all traces are labeled). For dim flashes the response amplitude increases linearly with intensity. At high intensities the receptor saturates and remains hyperpolarized steadily for some time after the flash; this leads to the afterimages that we perceive after a bright flash. Note that the response peaks earlier for brighter flashes and that cones respond faster than rods. (Reproduced, with permission, from Schneeweis and Schnapf 1995.)

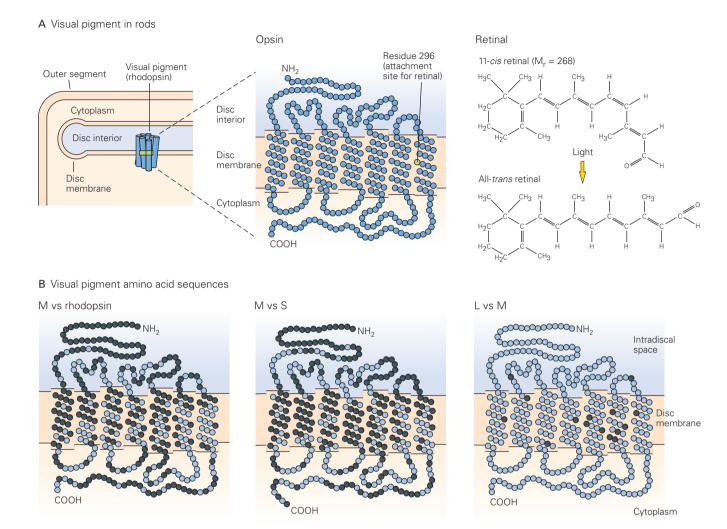

Figure 26-8 Structure of the visual pigments.

A. Rhodopsin, the visual pigment in rod cells, is the covalent complex of a large protein, opsin, and a small light-absorbing compound, retinal. Opsin has 348 amino acids and a molecular mass of approximately 40,000 daltons. It loops back and forth seven times across the membrane of the rod disc. Retinal is covalently attached to a side chain of lysine 296 in the protein's seventh membrane-spanning region. Absorption of light by 11-cis retinal causes a rotation around the double bond. As retinal adopts the more stable all-trans configuration, it causes a conformational change in the protein that triggers the subsequent events of visual

encoded by a decrease in firing rate. If the ganglion cell fired at a maintained rate of 10 spikes per second and then decreased its rate, it would take about 100 ms for the postsynaptic neuron to notice the change in frequency of action potentials. In contrast, an increase in firing rate to 200 spikes per second is noticeable within

only 5 ms.

transduction. (Adapted, with permission, from Nathans and Hogness 1984.)

B. Amino acid sequences of cone and rod pigments. Blue circles denote identical amino acids; black circles denote differences. The three types of cone opsins resemble each other and rhodopsin, suggesting that all four evolved from a common precursor by duplication and divergence. The L and M opsins are most closely related, with 96% identity in their amino acid sequences. They are thought to derive from a gene-duplication event approximately 30 million years ago, after Old World monkeys, which have three pigments, separated from New World monkeys, which generally have only two.

Many Ganglion Cells Respond Strongly to Edges in the Image

To probe the responses of a ganglion cell in more detail, one can focus a small spot of light on different portions of the retina to test how the cell's firing varies with the location and time course of the spot.

A typical ganglion cell is sensitive to light in a compact region of the retina near the cell body, called the cell's *receptive field*. Within that area one can often distinguish a *center* region and *surround* region in which light produces opposite responses. An ON cell, for example, fires faster when a bright spot shines on its receptive field's center but decreases its firing when the spot shines on the surround. If light covers both the center and the surround, the response is much weaker than for center-only illumination. A bright spot on the center combined with a dark annulus on the surround elicits very strong firing. For an OFF cell these relationships are reversed; the cell is strongly excited by a dark spot in a bright annulus (Figure 26–10).

The output produced by a population of retinal ganglion cells thus enhances regions of spatial contrast in the input, such as an edge between two areas of different intensity, and gives less emphasis to regions of homogeneous illumination.

The Output of Ganglion Cells Emphasizes Temporal Changes in Stimuli

When an effective light stimulus appears, a ganglion cell's firing typically increases sharply from the resting level to a peak and then relaxes to an intermediate rate. When the stimulus turns off, the firing rate drops sharply then gradually recovers to the resting level.

The rapidity of decline from the peak to the resting level varies among ganglion cell types. *Transient neurons* produce a burst of spikes only at the onset of the stimulus whereas *sustained neurons* maintain an almost

steady firing rate for several seconds during stimulation (Figure 26–10).

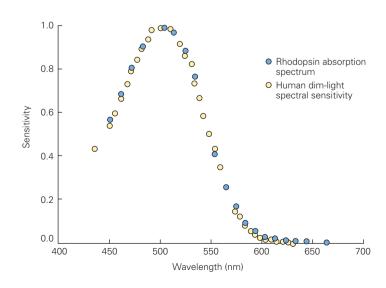

In general, however, the output of ganglion cells emphasizes temporal changes in the visual input over periods of constant light intensity. In fact, when the image is stabilized on the retina with an eyetracking device, it fades from view within seconds. Fortunately this never happens in normal vision; even when we attempt to fix our gaze, small automatic eye movements (saccades) continually scan the image across the retina and prevent the world from disappearing.

Retinal Output Emphasizes Moving Objects

Based on these observations we can understand more generally the response of ganglion cells to visual inputs. For example, a moving object elicits strong firing in the ganglion cell population near the edges of the object's image because these are the only regions of spatial contrast and the only regions where the light intensity changes over time (Figure 26–11).

We can imagine why the retina highlights these features. The outline of an object is particularly useful for inferring its shape and identity. Similarly, objects that move or change suddenly are more worthy of immediate attention than those that do not. Retinal processing thus extracts low-level features of the scene that are useful for guiding behavior and transmits those selectively to the brain. In fact, the rejection of features that are constant either in space or in time accounts for the spatiotemporal sensitivity of human perception (Box 26–1).

Figure 26–9 Absorption spectrum of rhodopsin. This plot compares the absorption spectrum of human rhodopsin measured in a cuvette and the spectral sensitivity of human observers to very dim light flashes. The psychophysical data have been corrected for absorption by the ocular media. (Reproduced, with permission, from Wald and Brown 1956.)

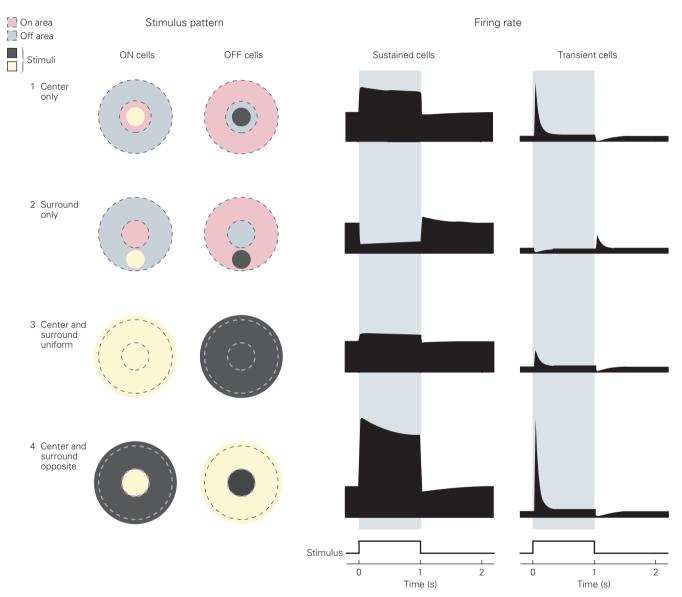

Figure 26–10 Responses of retinal ganglion cells with center-surround receptive fields. In these idealized experiments the stimulus changes from a uniform gray field to the pattern of bright (yellow) and dark (black) regions indicated on the left. 1. ON cells are excited by a bright spot in the receptive field center, OFF cells by a dark spot. In sustained cells the excitation persists throughout stimulation, whereas in transient

cells a brief burst of spikes occurs just after the onset of stimulation. 2. If the same stimulus that excites the center is applied to the surround, firing is suppressed. 3. Uniform stimulation of both center and surround elicits a response like that of the center, but much smaller in amplitude. 4. Stimulation of the center combined with the opposite stimulus in the surround produces the strongest response.

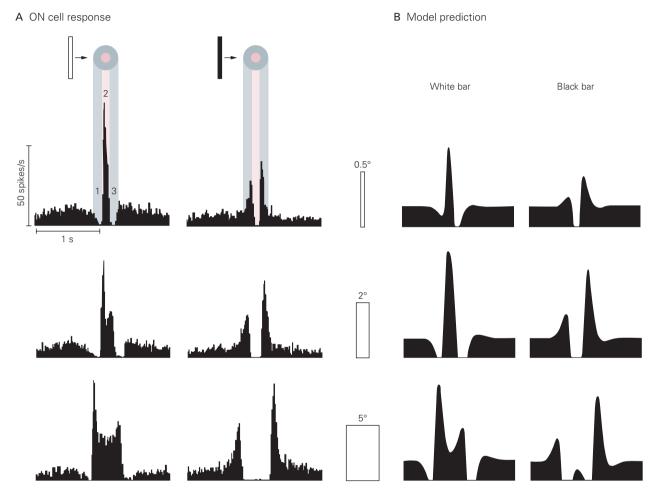

Figure 26–11 The representation of moving objects by retinal ganglion cells.

A. The firing rate of an ON ganglion cell in the cat's retina in response to a variety of bars (white or black, various widths) moving across the retina. Each bar moves at 10° per second; 1 degree corresponds to 180 µm on the retina. In response to the white bar the firing rate first decreases as the bar passes over the receptive-field surround (1), increases as the bar enters the center (2), and decreases again as the bar passes through the surround on the opposite side (3). The dark bar elicits responses of the opposite sign. Because retinal ganglion cells similar to this one are distributed throughout the retina, one can also interpret this curve as an instantaneous snapshot

of activity in many different ganglion cells, plotting firing rate as a function of location on the retina. In effect this is the neural representation of the moving bar transmitted to the brain. A complementary population of OFF ganglion cells (not shown here) conveys another neural image in parallel. In this way both bright edges and dark edges can be signaled by a sharp increase in firing.

B. A simple model of retinal processing that incorporates center-surround antagonism and a transient temporal filter is used to predict ganglion-cell firing rates. The predictions match the essential features of the responses in part A. (Reproduced, with permission, from Rodieck 1965.)

Box 26–1 Spatiotemporal Sensitivity of Human Perception

Whereas small spots of light are useful for probing the receptive fields of single neurons, different stimuli are needed to learn about human visual perception. One method to probe how our visual system deals with spatial and temporal patterns uses *grating stimuli*.

The subject views a display in which the intensity varies about the mean as a sinusoidal function of space (Figure 26–12). Then the contrast of the display—defined as the peak-to-peak amplitude of the sinusoid divided by the mean—is reduced to a threshold at which the grating is barely visible. One then repeats this measurement for gratings of different spatial frequencies, measuring the threshold contrast in each case.

Plotting the inverse of this threshold against the spatial frequency, one obtains the *contrast sensitivity curve*, a measure of sensitivity of visual perception to patterns of different scales (Figure 26–13A). When measured at high light intensity, sensitivity declines sharply at high spatial frequencies, with an absolute threshold at approximately 50 cycles per degree. This sensitivity is limited fundamentally by the quality of the optical image and the spacing of cone cells in the fovea (see Figure 26–1C).

Interestingly, sensitivity also declines at low spatial frequencies. Patterns with a frequency of approximately 5 cycles per degree are most visible. The visual system is said to have *band-pass* behavior because it rejects all but a band of spatial frequencies.

One can measure the sensitivity of individual ganglion cells to spatial contrast by stimulating the primate retina with the same displays. The results resemble those for human visual perception (Figure 26–13A), suggesting that the perceptual effects originate in the retina.

The band-pass behavior can be understood on the basis of spatial antagonism in center-surround receptive fields (Figure 26–13B). A very fine grating presents many dark and bright stripes within the receptive-field center;

their effects cancel one another and thus provide no net excitation. With a very coarse grating, a single stripe can cover both the center and surround of the receptive field, and their antagonism again provides the ganglion cell little net excitation. The strongest response is produced by a grating of intermediate spatial frequency that just covers the center with one stripe and most of the surround with stripes of the opposite polarity.

In dim light the visual system's contrast sensitivity declines, but more so at high than at low spatial frequencies (Figure 26–13A). Thus the peak sensitivity shifts to lower spatial frequencies, and eventually the curve loses its peak altogether. In this state the visual system has so-called *low-pass* behavior, for it selectively passes stimuli of low spatial frequency. It has been shown that the receptive fields of ganglion cell lose their antagonistic surrounds in dim light, which can explain this transition from band-pass to low-pass spatial filtering (Figure 26–13B).

Similar experiments can be done to test visual sensitivity to temporal patterns. Here the intensity of a test stimulus flickers sinusoidally in time, while the contrast is gradually brought to the threshold level of detection. For humans, contrast sensitivity declines sharply at very high flicker frequencies, but it also declines at very low frequencies (Figure 26–14A). Flicker at approximately 10 Hz is the most effective stimulus. One finds similar band-pass behavior in the flicker sensitivity of macaque retinal ganglion cells (Figure 26–14B).

Sensitivity to temporal contrast also depends on the mean light level. For human subjects the optimum flicker frequency shifts downward, and the peak in the curve becomes less and less prominent at lower stimulus intensities (Figure 26–14). The fact that primate retinal ganglion cells duplicate this behavior suggests that retinal processing limits visual perception in these simple tasks.

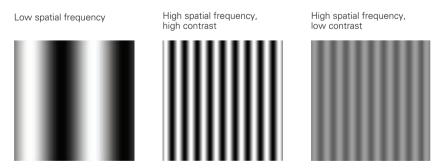

Figure 26–12 Sinusoid grating displays used in psychophysical experiments with human subjects. These

stimuli are employed in the experiments discussed in Figure 26–13.

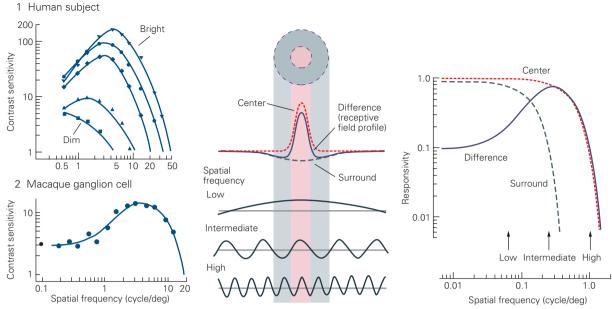

Figure 26-13 Spatial contrast sensitivity.

A. 1. Contrast sensitivity of human subjects. Using gratings at different spatial frequencies, the threshold contrast required for detection was measured and the inverse of that contrast value was plotted against spatial frequency. The curves were obtained at different mean intensities, decreasing by factors of 10 from the top to the bottom curve. (Reproduced, with permission, from DeValois, Morgan, and Snodderly 1974.) 2. Contrast sensitivity of a P-type ganglion cell in the macaque retina measured at high intensity. At each spatial frequency the contrast was gradually increased until it produced detectable modulation of the neuron's firing rate. The inverse of that threshold contrast was plotted as in part A. The isolated dot at left marks the sensitivity at zero spatial frequency, a spatially uniform field. (Reproduced, with permission, from Derrington and Lennie 1984.)

B. Stimulation of a center-surround receptive field with sinusoid gratings. The neuron's sensitivity to light at different points on the retina is modeled as a "difference-of-Gaussians" receptive field, with a narrow positive Gaussian for the excitatory center and a broad negative Gaussian for the inhibitory surround. Multiplying the spatial frequency with the receptive-field profile and integrating over all space calculates the stimulus strength delivered by a particular grating. The resulting sensitivity of the receptive field to gratings of different frequency is shown in the plot on the right. At low spatial frequencies the negative contribution from the surround cancels the contribution from the center, leading to a drop in the difference curve. (Reproduced, with permission, from Enroth-Cugell and Robson 1984.)

A Human subjects

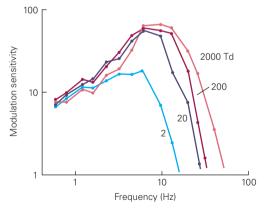

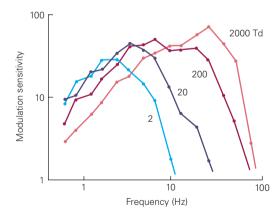

Figure 26–14 Temporal contrast sensitivity. (Reproduced, with permission, from Lee et al. 1990.)

A. Perceptual sensitivity of human observers. These measurements are similar to those in Figure 26–13, but the stimulus was a large spot, 4.6° in diameter, with an intensity that varied sinusoidally in time rather than space. The inverse of the minimal contrast required for detection is plotted against the flicker frequency. Sensitivity declines

B Macaque ganglion cells

at both high and low frequencies. The mean light level varied, decreasing by factors of 10 from the top to the bottom trace.

B. Sensitivity of M-type ganglion cells in the macaque retina. These experiments were identical to those on human subjects in part A. The detection threshold for the neural response was defined as a variation of 20 spikes per second in the cell's firing rate in phase with the flicker.

Several Ganglion Cell Types Project to the Brain Through Parallel Pathways

Several different types of ganglion cells have been identified on the basis of their shapes and light responses. The ON and OFF cells occur in every vertebrate retina, and in the primate retina two major classes of cells, the P-cells and M-cells, each include ON and OFF types (see Figure 26–2B). At any given distance from the fovea the receptive fields of M-cells (Latin *magno*, large) are much larger than those of P-cells (Latin *parvo*, small). The M-cells also have faster and more transient responses than P-cells. A type of ganglion cell discovered recently is intrinsically light-sensitive owing to expression of the visual pigment melanopsin.

In total about 20 ganglion-cell types have been described. Each type covers the retina in a tiled fashion, such that any point on the retina lies within the receptive field center of at least one ganglion cell. One can envision each separate population as sending a distinct neural representation of the visual field to the brain, where the firing of an individual ganglion cell represents one pixel in the representation. In this view the optic nerve conveys about 20 neural representations of the world that differ in polarity (ON or OFF), spatial resolution (fine or coarse), temporal responsiveness (sustained or transient), spectral filtering (broadband or dominated by red, green, or blue), and selectivity for other image features such as motion.

These neural representations are directed to various visual centers in the brain, including the lateral geniculate nucleus of the thalamus, a relay to the visual cortex; the superior colliculus, a midbrain region involved in spatial attention and orienting movements; the pretectum, involved in control of the pupil; the accessory optic system, which analyzes self-motion to stabilize gaze; and the suprachiasmatic nucleus, a central clock that directs circadian rhythm and whose phase can be set by light cues (Chapter 51). In many cases the same ganglion-cell type sends axon collaterals to multiple target areas; M-cells, for example, project to the thalamus and the superior colliculus.

A Network of Interneurons Shapes the Retinal Output

We now consider in more detail the basic retinal circuit and how it accounts for the intricate response properties of retinal ganglion cells.

Parallel Pathways Originate in Bipolar Cells

The photoreceptor forms synapses with bipolar cells and horizontal cells (see Figure 26–3A). In the dark the

cell's synaptic terminal releases glutamate continuously. On illumination the photoreceptor hyperpolarizes, less Ca²⁺ enters the terminal, and the terminal releases less glutamate. Photoreceptors do not fire action potentials; like bipolar cells they release neurotransmitter in a graded fashion using a specialized structure, the *ribbon synapse*. In fact, most retinal processing is accomplished with graded membrane potentials: Action potentials occur only in certain amacrine cells and in ganglion cells.

The two principal varieties of bipolar cells, ON and OFF cells, respond to glutamate at the synapse through distinct mechanisms. The OFF cells use ionotropic receptors, namely glutamate-gated cation channels of the AMPA-kainate variety (AMPA = $\alpha\text{-amino-}3\text{-hydroxy-}5\text{-methylisoxazole-}4\text{-propionate}).$ The glutamate released in darkness depolarizes these cells. The ON cells use metabotropic receptors that are linked to a G protein whose action ultimately closes cation channels. Glutamate activation of these receptors thus hyperpolarizes the cells in the dark.

Bipolar ON and OFF cells differ in shape and especially in the levels within the inner plexiform layer where their axons terminate. The axons of ON cells end in the proximal (lower) half, those of OFF cells in the distal (upper) half (Figure 26–15). There they form specific synaptic connections with amacrine and ganglion cells whose dendritic trees ramify in specific levels of the inner plexiform layer. The ON bipolar cells excite ON ganglion cells, while OFF bipolar cells excite OFF ganglion cells (see Figure 26–3A). Thus the two principal subdivisions of the retinal output signal, the ON and OFF pathways, are already established at the level of bipolar cells.

Bipolar cells can also be distinguished by the morphology of their dendrites (Figure 26–15). In the central region of the primate retina the *midget bipolar cell* receives input from a single cone and excites a P-type ganglion cell. This explains why the centers of P-cell receptive fields are so small. The *diffuse bipolar cell* receives input from many cones and excites an M-type ganglion cell. The receptive-field centers of M-cells are accordingly much larger. Thus stimulus representations in the ganglion cell population originate in dedicated bipolar cell pathways that are differentiated by their selective connections to photoreceptors and post-synaptic targets.

Spatial Filtering Is Accomplished by Lateral Inhibition

Signals in the parallel vertical pathways are modified by lateral interactions with horizontal and amacrine cells (see Figure 26–3A). Horizontal cells have broadly

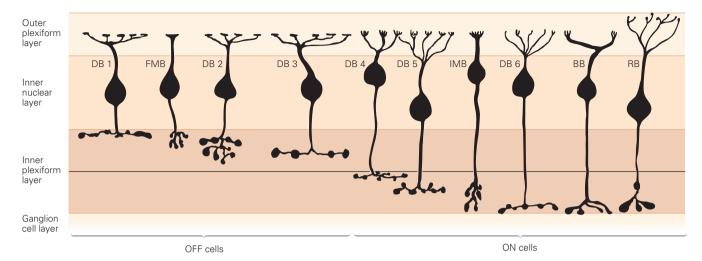

Figure 26–15 Bipolar cells in the macaque retina. The cells are arranged according to the depth of their terminal arbors in the inner plexiform layer. The horizontal line dividing the distal and proximal levels of this layer represents the border between the axonal terminals of OFF and ON types. Bipolar cells with

axonal terminals in the upper (distal) half are presumed to be OFF cells, those in the lower (proximal) half ON cells. Cell types are diffuse bipolar cells (DB), ON and OFF midget bipolars (IMB, FMB), S-cone ON bipolar (BB), and rod bipolar (RB). (Reproduced, with permission, from Boycott and Wässle 1999.)

arborizing dendrites that spread laterally in the outer plexiform layer. The tips of these arbors contact photoreceptors at terminals shared with bipolar cells. Glutamate released by the photoreceptors excites the horizontal cell. In addition, horizontal cells are electrically coupled with each other through gap junctions.

A horizontal cell effectively measures the average level of excitation of the photoreceptor population over a broad region. This signal is fed back to the photoreceptor terminal through an inhibitory synapse. Thus the photoreceptor terminal is under two opposing influences: light falling on the receptor hyperpolarizes it, but light falling on the surrounding region depolarizes it through the sign-inverting synapses from horizontal cells. As a result, the bipolar cell, which shares the photoreceptor's glutamatergic terminals with the horizontal cells, has an antagonistic receptive field structure.

This spatial antagonism in the receptive field is enhanced by lateral inhibition from amacrine cells in the inner retina. Amacrine cells are axonless neurons with dendrites that ramify in the inner plexiform layer. Approximately 30 types of amacrine cells are known, some with small arbors only tens of micrometers across, and others with processes that extend all across the retina. Amacrine cells generally receive excitatory signals from bipolar cells at glutamatergic synapses. Some amacrine cells feed back directly to the presynaptic bipolar cell at a *reciprocal inhibitory synapse*. Some amacrine cells are electrically coupled to others of the same

type, forming an electrical network much like that of the horizontal cells.

Through this inhibitory network a bipolar cell terminal can receive inhibition driven by other, distant bipolar cells, in a manner closely analogous to the lateral inhibition of photoreceptor terminals (see Figure 26–3A). Amacrine cells also inhibit retinal ganglion cells directly. These lateral inhibitory connections contribute substantially to the antagonistic receptive field component of retinal ganglion cells.

Temporal Filtering Occurs in Synapses and Feedback Circuits

For many ganglion cells a step change in light intensity produces a transient response, an initial peak in firing that declines to a smaller steady rate (see Figure 26–10). Part of this sensitivity originates in the negative-feedback circuits involving horizontal and amacrine cells.

For example, a sudden decrease in light intensity depolarizes the cone terminal, which excites the horizontal cell, which in turn repolarizes the cone terminal (see Figure 26–3A). Because this feedback loop involves a brief delay, the voltage response of the cone peaks abruptly and then settles to a smaller steady level. Similar processing occurs at the reciprocal synapses between bipolar and amacrine cells in the inner retina.

In both cases the delayed-inhibition circuit favors rapidly changing inputs over slowly changing inputs. The effects of this filtering, which can be observed in visual perception, are most pronounced for large stimuli that drive the horizontal cell and amacrine cell networks most effectively. For example, a large spot can be seen easily when it flickers at a rate of 10 Hz but not at a low rate (see Figure 26–14).

In addition to these circuit properties, certain cellular processes contribute to shaping the temporal response. For example, the AMPA-kainate type of glutamate receptor undergoes strong desensitization. A step increase in the concentration of glutamate at the dendrite of a bipolar or ganglion cell leads to an immediate opening of additional glutamate receptors. As these receptors desensitize, the postsynaptic conductance decreases again. The effect is to render a step response more transient.

Retinal circuits seem to go to great lengths to speed up their responses and emphasize temporal changes. One likely reason is that the very first neuron in the retinal circuit, the photoreceptor, is exceptionally slow (see Figure 26–7C). Following a flash of light a cone takes about 40 ms to reach the peak response, an intolerable delay for proper visual function. Through the various filtering mechanisms in retinal circuitry, subsequent neurons respond sensitively during the rising phase of the cone's response. Indeed, some ganglion cells have a response peak only 20 ms after the flash. Temporal processing in the retina clearly helps to reduce visual reaction times, a life-extending trait in highway traffic as on the savannas of our ancestors.

Color Vision Begins in Cone-Selective Circuits

Throughout recorded history philosophers and scientists have been fascinated by the perception of color. This interest was fueled by the relevance of color to art, later by its relation to the physical properties of light, and finally by commercial interests in television and photography. The 19th century witnessed a profusion of theories to explain color perception, of which two have survived modern scrutiny. They are based on careful psychophysics that placed strong constraints on the underlying neural mechanisms.

Early experiments on color matching showed that the percept of any given light could be matched by mixing together appropriate amounts of three primary lights. Thomas Young and Hermann von Helmholtz accordingly postulated the trichromatic theory of color perception based on absorption of light by three mechanisms, each with a different sensitivity spectrum. We now know that these correspond to the three cone types (see Figure 26–6), whose measured absorption spectra fully explain the color-matching results both in

normal individuals and those with genetic anomalies in the pigment genes.

In an effort to explain our perception of different hues, Ewald Hering proposed the opponent-process theory, later formalized by Leo Hurvich and Dorothea Jameson. According to this theory, color vision involves three processes that respond in opposite ways to light of different colors: (y–b) would be stimulated by yellow and inhibited by blue light; (r–g) stimulated by red and inhibited by green; and (w–bk) stimulated by white and inhibited by black. We can now recognize some of these processes in the post-receptor circuitry of the retina.

In the central 10° of the human retina a single midget bipolar cell that receives input from a single cone excites each P-type ganglion cell. An L-ON ganglion cell, for example, has a receptive field center consisting of a single L cone and an antagonistic surround involving a mixture of L and M cones. When stimulated with a large spot that extends over both the center and the surround, this neuron is depolarized by red light and hyperpolarized by green light. Similar antagonism holds for the three other P-cells: L-OFF, M-ON, and M-OFF. These P-cells send their signals to the parvocellular layers of the lateral geniculate nucleus.

Although S cones are relatively rare, a dedicated type of S-ON bipolar cell collects their signals selectively and transmits them to ganglion cells of the small bistratified type. Because this ganglion cell also receives excitation from L-OFF and M-OFF bipolar cells, it is depolarized by blue light and hyperpolarized by yellow light. Another ganglion cell type shows the opposite signature: S-OFF and (L + M)-ON. These signals are transmitted to the koniocellular layers of the lateral geniculate nucleus.

The M cells are excited by diffuse bipolar cells, which in turn collect inputs from many cones regardless of pigment type. These ganglion cells therefore have large receptive fields with broad spectral sensitivity. Their axons project to the magnocellular layers of the lateral geniculate nucleus.

In this way chromatic signals are combined and formatted by the retina for transmission to the thalamus and cortex. In the primary visual cortex these signals are recombined in different ways, leading to a great variety of receptive field layouts. Note that only about 10% of cortical neurons are preferentially driven by color contrast rather than luminance contrast. This likely reflects the fact that color vision—despite its great esthetic appeal—makes only a small contribution to our overall fitness. As an illustration of this, recall that colorblind individuals, who in a sense have lost half of their color space, can grow up without noticing that defect.

Congenital Color Blindness Takes Several Forms

Few people are truly colorblind in the sense of being wholly unable to distinguish a change in color from a change in the intensity of light, but many individuals have impaired color vision and experience difficulties in making distinctions that for most of us are trivial, for example between red and green. Most such abnormalities of color vision are congenital and have been characterized in detail; some other abnormalities result from injury or disease of the visual pathway.

The study of inherited variation in color vision has contributed in important ways to our understanding of the mechanisms of normal color vision. The first major insight, well understood in the 19th century, is that some people have only two classes of receptors instead of the three in normal trichromatic vision. These dichromats find it difficult or impossible to distinguish some surfaces whose colors appear distinct to trichromats. The dichromat's problem is that every surface reflectance function is represented by a two-value description rather than a three-value one, and this reduced description causes dichromats to confuse many more surfaces than do trichromats. Simple tests for color-blindness exploit this fact. Figure 26–16 shows an example from the Ishihara test, in which the numerals defined by colored dots are seen by normal trichromats but not by most dichromats.

When a person with normal color vision fails to distinguish two physically different surface reflectance functions, a dichromat will also fail to distinguish them. This failure means that each class of cone gives rise to the same signal when absorbing light reflected by either surface, so the fact that the dichromat is confused by the same surfaces that confuse a trichromat shows that the cones in the dichromat have normal pigments.

Although there are three forms of dichromacy, corresponding to the loss of each of the three types of cones, two kinds of dichromacy are much more common than the third. The common forms correspond to the loss of the L cones or M cones and are called *protanopia* and *deuteranopia*, respectively. Protanopia and deuteranopia almost always occur in males, each with a frequency of about 1%. The conditions are transmitted by women who are not themselves affected, and so implicate genes on the X chromosome. A third form of dichromacy, *tritanopia*, corresponds to the loss or dysfunction of the S cone. It affects only about 1 in 10,000 people, afflicts women and men with equal frequency and has a gene on chromosome 7.

Because the L and M cones exist in large numbers, one might think that the loss of one or the other type

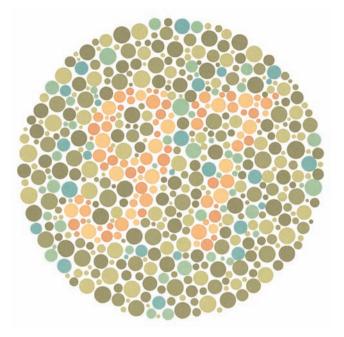

Figure 26–16 A test for some forms of color blindness. The numerals embedded in this color pattern can be distinguished by people with trichromatic vision but not by certain dichromats, including the Editor of this section of the book, who are weak in red–green discrimination. (Reproduced, with permission, from Ishihara 1993.)

would impair vision more broadly than just weakening color vision. In fact, this does not happen because the total number of L and M cones in the dichromat retina is not altered. All cells destined to become L or M cones are probably converted to L cones in deuteranopes and to M cones in protanopes.

In addition to the relatively severe forms of colorblindness represented by dichromacy, there are milder forms, again affecting mostly males, that result in an impaired capacity to distinguish different reflectance functions that are readily distinguished by normal trichromats. People with these milder impairments are referred to as anomalous trichromats, for their cones provide three-value descriptions of the light reflected by surfaces. In contrast to dichromats, however, they do not see as identical the physically different spectral functions distinguished by a normal trichromat.

These anomalous trichromats have cones whose spectral sensitivities differ from those of cones in normal trichromats. Anomalous trichromacy occurs in different forms, corresponding to the replacement of one of the normal cone pigments by an altered protein with a different spectral sensitivity. Two common forms, protanomaly and deuteranomaly, together affect about

7% of males and represent respectively the replacement of the L or M cones by a pigment with some intermediate spectral sensitivity.

The occurrence of sex-linked inherited defects of color vision points to the X chromosome as the locus of genes that encode the visual pigments of L and M cones. These genes, and the amino acid sequences of the pigments they encode, have now been identified, largely through the work of Jeremy Nathans and his colleagues. Their discovery reveals some interesting complexities in the molecular organization underlying color vision. Molecular cloning of the genes for the L and M pigments shows the genes to be very similar and arranged head-to-tail on the X chromosome (Figure 26–17A). The pigments also have very similar structures, differing in only 4% of their amino acids.

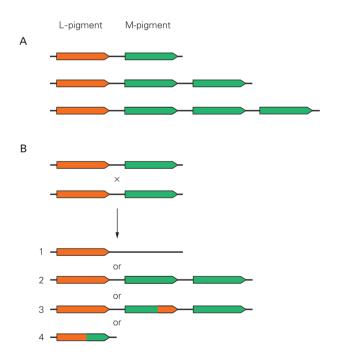

Figure 26–17 L- and M-pigment genes on the X chromosome.

A. Arrangement of L- and M-pigment genes in color-normal males. The base of each arrow corresponds to the 5' end of the gene, and the tip corresponds to the 3' end. Males with normal color vision can have one, two, or three copies of the gene for the M pigment on each X chromosome. (Adapted, with permission, from Nathans, Thomas, and Hogness 1986.)

B. Because they lie next to each other on the chromosome, the L- and M-pigment genes can undergo recombinations that lead to the generation of a hybrid gene (3 and 4) or the loss of a gene (1), the patterns observed in colorblind men. Spurious recombination can also cause gene duplication (2), a pattern observed in some people with normal color vision. (Adapted, with permission, from Stryer 1988.)

People with normal color vision possess a single copy of the gene for the L pigment and from one to three—occasionally as many as five—nearly identical copies of the gene for the M pigment.

The proximity and similarity of these genes is thought to predispose them to varied forms of recombination, leading either to the loss of a gene or to the formation of hybrid genes that account for the common forms of red-green defect (Figure 26–17B). Examination of these genes in dichromats reveals a loss of the L-pigment gene in protanopes and a loss of one or more M-pigment genes in deuteranopes. Anomalous trichromats have L-M or M-L hybrid genes that code for visual pigments with shifted spectral sensitivity, the extent of the shift depending on the point of recombination. In tritanopes, the loss of S-cone function arises from mutations in the S-pigment gene.

Rod and Cone Circuits Merge in the Inner Retina

For vision under low-light conditions the mammalian retina has an ON bipolar cell that is exclusively connected to rods (see Figure 26–3B). By collecting inputs from up to 50 rods, this rod bipolar cell can pool the effects of dispersed single-photon absorptions in a small patch of retina. This neuron is excited by light and there is no corresponding OFF bipolar cell dedicated to rods.

Unlike all other bipolar cells, the rod bipolar cell does not contact ganglion cells directly but instead excites a dedicated neuron called the AII amacrine cell. This amacrine cell receives inputs from several rod bipolar cells and conveys its output to cone bipolar cells. It sends excitatory signals to ON bipolar cells through gap junctions as well as glycinergic inhibitory signals to OFF bipolar cells. These cone bipolar cells in turn excite ON and OFF ganglion cells as described above. Thus the rod signal is fed into the cone system after a detour, involving the rod bipolar and AII amacrine cells, that produces the appropriate signal polarities for the ON and OFF pathways. The purpose of these added interneurons may be to allow greater pooling of rod signals than of cone signals.

Rod signals also enter the cone system through two other pathways. Rods can drive neighboring cones directly through electrical junctions, and they make connections with an OFF bipolar cell that services primarily cones. Once the rod signal has reached the cone bipolars through these pathways, it can take advantage of the same intricate circuitry of the inner retina. One gets the impression that the rod system of the mammalian retina is an evolutionary afterthought added to the cone circuits.

The Retina's Sensitivity Adapts to Changes in Illumination

Vision operates under many different lighting conditions. The intensity of the light coming from an object depends on the intensity of the illuminating light and the fraction of this light reflected by the object's surface, called the *reflectance*. The range of intensities encountered in a day is enormous, with variation spanning 10 orders of magnitude, but most of this variation is useless for the purpose of guiding behavior.

The illuminant intensity varies by about nine logarithmic units, mostly because our planet turns about its axis once a day, while the object reflectance varies much less, by about one order of magnitude in a typical scene. But this reflectance is the interesting quantity for vision, for it characterizes objects and distinguishes them from the background. In fact, our visual system is remarkably good at calculating surface reflectances independently of the illuminant intensity (Figure 26–18).

When illumination becomes stronger, all points in the retinal image increase in intensity by the same factor. If the retina could simply reduce its sensitivity by the same factor, the neural representation of the retinal image would remain unchanged at the level of the ganglion cells and could be processed by the rest of the brain in the same way as before the change in illumination. Moreover, the retinal ganglion cells would only need to encode the tenfold range of image intensities owing to the different object reflectances, instead of the 10-billionfold range that includes variations in illumination. In fact, the retina does perform such an automatic gain control, called *light adaptation*, that approaches the ideal normalization we have imagined here.

Light Adaptation Is Apparent in Retinal Processing and Visual Perception

The responses of a retinal ganglion cell to varying flashes of light with a steady background illumination fit a sigmoidal curve (Figure 26–19A). The weakest flashes elicit

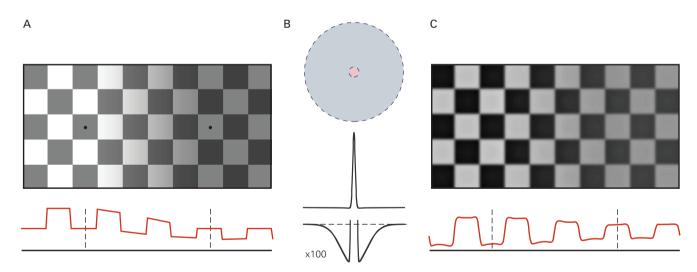

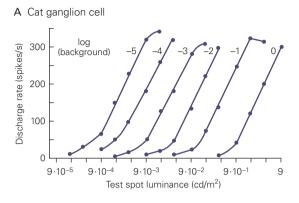

Figure 26–18 A brightness illusion.

A. The two tiles marked with small dots appear to have different brightness but actually reflect the same light intensity. (To see this, fold the page so they touch.) The trace underneath plots a profile of light intensity at the level of the arrowheads. Your visual system interprets this retinal image as a regular tile pattern under graded illumination with a diffuse shadow in the right half. Perceptual processing tries to discount this shadow to extract the underlying surface reflectance, and thus assigns a greater lightness to the right tile than the left. As you can see, this process is automatic and requires no conscious analysis.

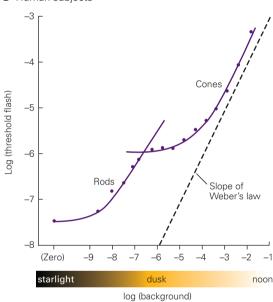

B. Retinal processing contributes to the perception of "lightness" by discounting the shadow's smooth gradients of

illumination and accentuating the sharp edges between checkerboard fields. The profile of the receptive field for a visual neuron with an excitatory center and an inhibitory surround is shown at the top. As shown in a hundredfold magnification at the bottom, the surround is weak but extends over a much larger area than the center.

C. The result when a population of visual neurons with receptive fields as in B processes the image in A. This operation—the convolution of the image in A with the profile in B—subtracts from each point in the input image the average intensity in a large surrounding region. The output image has largely lost the effects of shading, and the two tiles in question do indeed have different lightness values in this representation.

A. Light adaptation in a cat's retinal ganglion cell. The receptive field was illuminated uniformly at a steady background intensity, and a test spot was flashed briefly on the receptive field center. The peak firing rate following the flash was measured and plotted against the logarithm of the flash intensity. Each curve corresponds to a different background intensity, increasing by factors of 10 from left to right. (Reproduced, with permission, from Sakmann and Creutzfeldt 1969.)

B. Light adaptation in human vision. A small test spot was flashed briefly on a steadily illuminated background, and the intensity at which human subjects just detected the flash is plotted against the background intensity. The curve has two branches connected by a distinct kink: These correspond to the regimes of rod-and-cone vision. The slope of Weber's law represents the idealization in which the threshold intensity is

proportional to the background intensity. (Reproduced, with permission, from Wyszecki and Stiles 1967.)

C. Light adaptation in the macaque monkey. The top plot shows the responses of a macaque monkey's rod cell to flashes delivered at varying background intensities. The cell's single-photon response was calculated from the recorded membrane potential divided by the number of rhodopsins (Rh) activated by the flash. The gain of the single-photon response decreases substantially with increasing background intensity. The background intensity, in photon/µm²/s, is 0 for trace 0, 3.1 for trace 1, 12 for trace 2, 41 for trace 3, 84 for trace 4, and 162 for trace 5. In the bottom plot the same data (except for the smallest response) are normalized to the same amplitude, showing that the time course of the single-photon response accelerates at high intensity. (Reproduced, with permission, from Schneeweis and Schnapf 2000.)

no response, a graded increase in flash intensity elicits graded responses, and the brightest flashes elicit saturation. When the background illumination is increased, the response curve maintains the same shape but is shifted to higher flash intensities. Compensating for the increase in background illumination, the ganglion cell is now less sensitive to light variations: In the presence of a higher background, a larger change is needed to cause the same response. This lateral shifting of the stimulus-response relationship is a hallmark of light adaptation in the retina.

The consequences of this gain change for human visual perception are readily apparent in psychophysical experiments. When a human subject is asked to detect a flash on a background field of constant illumination, a brighter background necessitates brighter flashes for detection (Figure 26–19B). Under the ideal gain-control mechanism discussed above, two stimuli would produce the same response if they caused the same fractional change from the background intensity. In that case the threshold flash intensity should be proportional to the background intensity, a relationship known as Weber's law of adaptation, which we encountered in considering somatic sensitivity (Chapter 21). The visual system follows Weber's law approximately: Over the entire range of vision, sensitivity decreases somewhat less steeply with increasing background intensity (Figure 26–19B).

Multiple Gain Controls Occur Within the Retina

Light adaptation occurs at multiple sites within the retina that together produce the enormous changes in gain that are required. In starlight a single rod cell is stimulated by a photon only every few seconds, a rate insufficient to alter the cell's adaptation status. However, a retinal ganglion cell combines signals from many rods, thus receiving a steady stream of photon signals that can elicit a light-dependent gain change in the cell.

At somewhat higher light intensities a rod bipolar cell begins to adapt, changing its responsiveness depending on the average light level. Next we reach a light intensity at which the gain of individual rod cells gradually decreases. Beyond that the rods saturate: All their cGMP-dependent channels are closed, and the membrane potential no longer responds to the light stimulus. By this time, around dawn, the much less sensitive cone cells are being stimulated effectively and gradually take over from the rods. As the illumination increases further toward noon, light adaptation results principally from gain changes within the cones.

The cellular mechanisms of light adaptation are best understood in the photoreceptors. The Ca²⁺-dependent feedback pathways discussed above have a prominent role. Recall that when a light flash closes the cGMPgated channels, the resulting decrease in intracellular Ca2+ accelerates several biochemical reactions that terminate the response to the flash (see Figure 26–7B). When illumination is continuous the Ca2+ concentration remains low, and all these reactions are therefore in a steady state that both lowers the gain and accelerates the time course of the receptor's response to light (Figure 26–19C). As a result, the light-adapted photoreceptor can respond to rapid changes in intensity much more quickly. This has important consequences for human visual perception; the contrast sensitivity to high-frequency flicker increases with intensity, an effect observed in primate retinal ganglion cells as well (see Figure 26–14).

Light Adaptation Alters Spatial Processing

In addition to the sensitivity and speed of the retinal response, light adaptation also changes the rules of spatial processing. In bright light many ganglion cells have a sharp center-surround structure in their receptive fields (see Figure 26–10). As the light dims, the antagonistic surround becomes broad and weak and eventually disappears. Under these conditions the ganglion cell is concerned with accumulating the rare photons over its receptive field rather than computing local intensity gradients. These changes in receptive-field properties occur because of changes in the lateral inhibition produced by the networks of horizontal and amacrine cells (see Figure 26–3). An important regulator of these processes is dopamine, released in a light-dependent manner by specialized amacrine cells.

These retinal effects leave their signature on human perception. In bright light our visual system prefers fine gratings to coarse gratings. But in dim light we are most sensitive to coarse gratings: With the loss of center-surround antagonism, the low spatial frequencies are no longer attenuated (see Box 26–1 and Figure 26–13).

In conclusion, light adaptation has two important roles. One is to discard information about the intensity of ambient light while retaining information about object reflectances. The other is to match the small dynamic range of firing in a retinal ganglion cell to the large range of light intensities in the environment. The retina must accomplish these large gain changes with graded neuronal signals before action potentials are produced in optic nerve fibers, for their firing rates can vary effectively over only two orders of magnitude.

In fact, the crucial need for light adaptation may be why the neural circuitry resides in the eye and not in the brain at the other end of the optic nerve.

An Overall View

The retina transforms light patterns projected onto photoreceptors into neural signals that are conveyed through the optic nerve to specialized visual centers in the brain. Different populations of ganglion cells transmit multiple neural representations of the retinal image along parallel pathways.

In producing its output the retina discards much of the stimulus information available at the receptor level and extracts certain low-level features of the visual field useful to the central visual system. Fine spatial resolution is maintained only in a narrow region at the center of gaze. Intensity gradients in the image, such as object edges, are emphasized over spatially uniform portions; temporal changes are enhanced over unchanging parts of the scene.

The retina adapts flexibly to the changing conditions for vision, especially the large diurnal changes in illumination. With increases in average light level the retina becomes progressively less sensitive, so that the response to a fractional change in intensity is almost independent of the overall illumination. Information about the absolute light level is largely discarded, favoring the subsequent analysis of object reflectances within the scene.

The transduction of light stimuli begins in the outer segment of the photoreceptor cell when a pigment molecule absorbs a photon. This sets in motion an amplifying G protein cascade that ultimately reduces the membrane conductance, hyperpolarizes the photoreceptor, and decreases glutamate release at the synapse. Multiple feedback mechanisms, in which intracellular Ca²+ has an important role, serve to turn off the enzymes in the cascade and terminate the light response.

Rod photoreceptors are efficient collectors of light and serve nocturnal vision. Cones are much less sensitive and function throughout the day. Cones synapse onto bipolar cells that in turn excite ganglion cells. Rods connect to specialized rod bipolar cells whose signals are conveyed through amacrine cells to the cone bipolar cells. These vertical excitatory pathways are modulated by horizontal connections that are primarily inhibitory. Through these lateral networks light in the receptive-field surround of a ganglion cell counteracts the effect of light in the center. The same negative-feedback circuits also sharpen the transient response of ganglion cells.

As we shall see in subsequent chapters, the segregation of information into parallel pathways and the shaping of response properties by inhibitory lateral connections are pervasive organizational principles in the visual system.

Cognitive Processes Influence Visual Perception

An Overall View

The Have seen in the preceding chapter that the eye is not a mere camera but instead contains sophisticated retinal circuitry that decomposes the retinal image into signals representing contrast and movement. These data are conveyed through the optic nerve to the primary visual cortex, which uses this information to analyze the shape of objects. It first identifies the boundaries of objects, represented by numerous short line segments, each with a specific orientation. The cortex then integrates this information into a representation of specific objects, a process referred to as *contour integration*.

These two steps, local analysis of orientation and contour integration, exemplify two distinct stages of visual processing. Computation of local orientation is an example of low-level visual processing, which is concerned with identifying local elements of the light structure of the visual field. Contour integration is an example of intermediate-level visual processing, the first step in generating a representation of the unified visual field. At the earliest stages of analysis in the cerebral cortex these two levels of processing are accomplished together.

A visual scene comprises many thousands of line segments and surfaces. Intermediate-level visual processing is concerned with determining which boundaries and surfaces belong to specific objects and which are part of the background (see Figure 25–4). It is also involved in distinguishing the lightness and color of a surface from the intensity and wavelength of light reflected from that surface. The physical characteristics of reflected light result as much from the intensity and color balance of the light that illuminates a surface as from the color of that surface. Determining the actual surface color of a single object requires comparison of the wavelengths of light reflected from multiple surfaces in a scene.

Intermediate-level visual processing thus involves assembling local elements of an image into a unified percept of objects and background. Although determining which elements belong together in a single object is a highly complex problem with the potential for an astronomical number of solutions, the brain has built-in logic that allows it to make assumptions about the likely spatial relationships between elements. In certain cases these inherent rules can lead to the illusion of contours and surfaces that do not actually exist in the visual field (Figure 27–1).

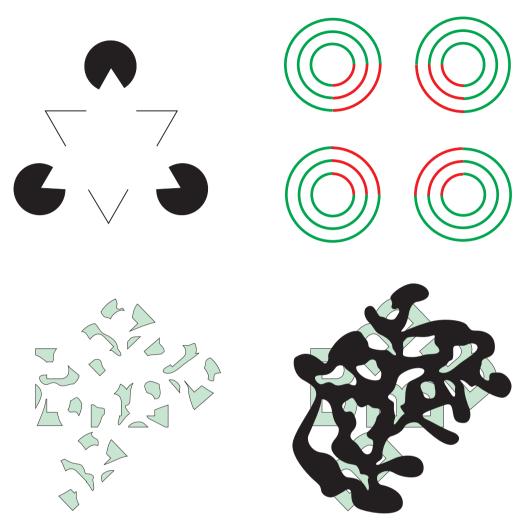

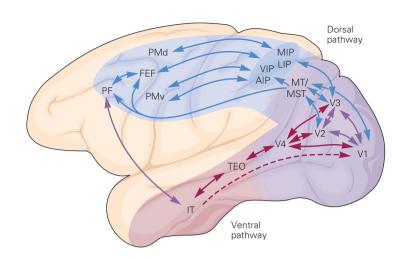

Figure 27–1 Illusory contours and perceptual fill-in. The visual system uses information about local orientation and contrast to construct the contours and surfaces of objects. This constructive process can lead to the perception of contours and surfaces that do not appear in the visual field, including those seen in illusory figures. In the Kanizsa triangle illusion (top left) one perceives continuous boundaries extending between the apices of a white triangle, even though the only real contour elements are those formed by the Pac-Man-like figures and the

acute angles. The inside and outside of the illusory pink square (top right) are the same white color as the page, but a continuous transparent pink surface within the square is perceived. As seen in the lower figures, contour integration and surface segmentation can also occur through occluding surfaces. The irregular shapes on the left appear to be unrelated, but when a partially occluding black area is overlaid on them (right) they are easily seen as fragments of the letter B.

First, context plays an important role in overcoming ambiguity in the signals from the retina. The way in which a visual feature is perceived depends on everything that surrounds that feature. The perception of a point or a line depends on how that object is perceptually linked to other visual features. Thus the response of a neuron in the visual cortex is context-dependent: It depends as much on the presence of contours and surfaces outside the cell's receptive field as on the attributes within it. Second, the functional properties

of neurons in the visual cortex are highly dynamic and can be altered by visual experience or perceptual learning. Finally, visual processing in the cortex is subject to the influence of cognitive functions, specifically attention, expectation, and "perceptual task," ie, the active engagement in visual discrimination or detection. The interaction between these three factors—visual context, experience-dependent changes in cortical circuitry, and expectation—is vital in the visual system's analysis of complex scenes.

Figure 27-2 Cortical areas involved with intermediate-level visual processing. Many cortical areas in the macague monkey, including V1, V2, V3, V4, and middle temporal area (MT), are involved with integrating local cues to construct contours and surfaces and segregating foreground from background. The shaded areas extend into the frontal and temporal lobes because cognitive output from these areas, including attention, expectation, and perceptual task, contribute to the process of scene segmentation. (AIP, anterior intraparietal cortex; FEF, frontal eye fields; IT, inferior temporal cortex: LIP. lateral intraparietal cortex: MIP. medial intraparietal cortex; MST, medial superior temporal cortex; MT, middle temporal cortex; PF, prefrontal cortex; PMd, dorsal premotor cortex; PMv, ventral premotor cortex; TEO, occipitotemporal cortex; VIP, ventral intraparietal cortex; V1, V2, V3, V4, primary, secondary, third, and fourth visual areas.)

In this chapter we examine how the brain's analysis of the local features in a visual scene, or *visual primitives*, proceeds in parallel with the analysis of more global features. Visual primitives include contrast, line orientation, brightness, color, movement, and depth.

Each type of visual primitive is subject to the integrative action of intermediate-level processing. Lines with particular orientations are integrated into object contours, local contrast information into surface lightness, wavelength selectivity into color constancy and surface segmentation, and directional selectivity into object motion. The analysis of visual primitives begins in the retina with the detection of brightness and color and continues in the primary visual cortex with the analysis of orientation, direction of movement, and stereoscopic depth. Properties related to intermediatelevel visual processing are analyzed together with visual primitives in the visual cortex starting in the primary visual cortex (V1), which plays a role in contour integration and surface segmentation. Other areas of the visual cortex specialize in different aspects of this task: V2 analyzes properties related to object surfaces, V4 integrates information about color and object shape, and V5—the middle temporal area or MT—integrates motion signals across space (Figure 27–2).

Internal Models of Object Geometry Help the Brain Analyze Shapes

A first step in determining an object's contour is identification of the orientation of local parts of the contour. This step commences in V1, which plays a critical role in both local and global analysis of form.

Neurons in the visual cortex respond selectively to specific local features of the visual field, including orientation, binocular disparity or depth, and direction of movement, as well as to properties already analyzed in the retina and lateral geniculate nucleus, such as contrast and color. Orientation selectivity, the first emergent property identified in the receptive fields of cortical neurons, was discovered by David Hubel and Torsten Wiesel in 1959.

Neurons in the lateral geniculate nucleus have circular receptive fields with a center-surround organization (see Chapter 25). They respond to the light-dark contrasts of edges or lines in the visual field but are not selective for the orientations of those edges. In the visual cortex, however, neurons respond selectively to lines of particular orientations. Each neuron responds to a narrow range of orientations, approximately 40°, and different neurons respond optimally to distinct orientations. There is now good evidence for the idea, first proposed by Hubel and Wiesel, that this orientation selectivity reflects the arrangement of the inputs from cells in the lateral geniculate nucleus. Each V1 neuron receives input from several neighboring geniculate neurons whose center-surround receptive fields are aligned so as to represent a particular axis of orientation (Figure 27–3).

Two principal types of orientation-selective neurons have been identified. *Simple cells* have receptive fields divided into ON and OFF subregions (Figure 27–4). When a visual stimulus such as a bar of light enters the receptive field's ON subregion, the neuron fires; the cell also responds when the bar leaves the OFF subregion. Simple cells have a characteristic response to a moving bar; they discharge briskly when a bar of light leaves an OFF region and enters an ON region.

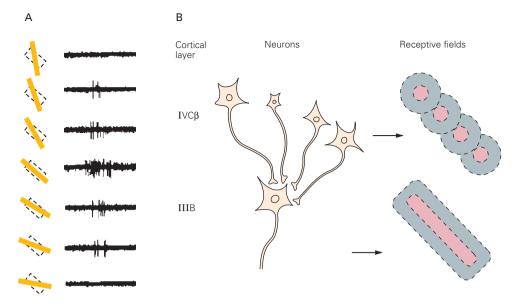

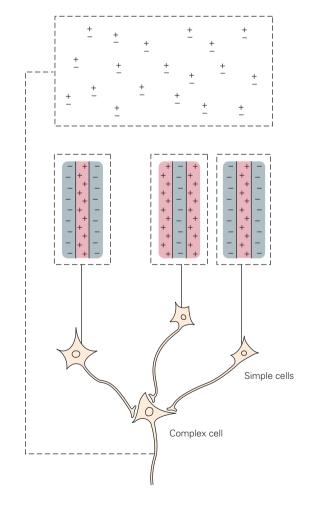

Figure 27–3 Orientation selectivity and mechanisms.

A. A neuron in the primary visual cortex responds selectively to line segments that fit the orientation of its receptive field. This selectivity is the first step in the brain's analysis of an object's form. (Reproduced, with permission, from Hubel and Wiesel 1968.)

B. The orientation of the receptive field is thought to result from the alignment of the circular center-surround receptive fields of several presynaptic cells in the lateral geniculate nucleus. In the monkey, neurons in layer IVC β of V1 have unoriented receptive fields. However, the projections of neighboring IVC β cells onto a neuron in layer IIIB create a receptive field with a specific orientation.

Figure 27–4 Simple and complex cells in the visual cortex. The receptive fields of simple cells are divided into subfields with opposite response properties. In an ON subfield, designated by "+," the onset of a light triggers a response in the neuron; in an OFF subfield, indicated by "-," the extinction of a bar of light triggers a response. Complex cells have overlapping ON and OFF regions and respond continuously as a line or edge traverses the receptive field along an axis perpendicular to the receptive-field orientation.

The responses of these cells are therefore highly selective for the position of a line or edge in space.

Complex cells, in contrast, are less selective for the position of object boundaries. They lack discrete ON and OFF subregions and respond similarly to light and dark at all locations across their receptive fields. They fire continuously as a line or edge stimulus traverses their receptive fields.

Moving stimuli are often used to study the receptive fields of visual cortex neurons, not only to simulate the conditions under which an object moving in space is detected but also to simulate the conditions under which stationary objects are tracked by the eyes, which constantly scan the visual environment and therefore move the boundaries of stationary objects across the retina. In fact, visual perception requires eye movement. Visual cortex neurons do not respond to an image that is stabilized on the retina because they require moving or flashing stimuli to be activated: They fire in response to transient stimulation.

Some visual cortex neurons have receptive fields in which an excitatory center is flanked by inhibitory regions. Inhibitory regions along the axis of orientation, a property known as *end-inhibition*, restrict a neuron's responses to lines of a certain length (Figure 27–5). Endinhibited neurons respond well to a line that does not extend into the inhibitory flanks but lies entirely within the excitatory part of the receptive field. Because the inhibitory regions share the orientation preference of the central excitatory region, end-inhibited cells are selective for line curvature and also respond well to corners.

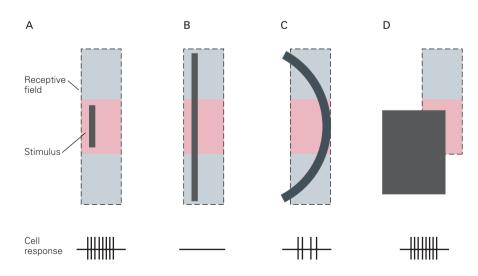

To define the shape of the object as a whole, the visual system must integrate the information on local

orientation and curvature into object contours. The way in which the visual system integrates contours reflects the geometrical relationships present in the natural world (Figure 27–6). As originally pointed out by Gestalt psychologists early in the 20th century, contours that are immediately recognizable tend to follow the rule of good continuation: Curved lines maintain a constant radius of curvature and straight lines stay straight. In a complex visual scene such smooth contours tend to "pop out," whereas more jagged contours are difficult to detect.

The responses of a visual cortex neuron can be modulated by stimuli that themselves do not activate the cell and therefore lie outside the receptive field's core. This *contextual modulation* endows a neuron with selectivity for more complex stimuli than would be predicted by placing the components of a stimulus at different positions in and around the receptive field. The same factors that facilitate the detection of an object in a complex scene (Figure 27–6A) also apply to contextual modulation. The properties of perceptible contours are reflected in the responses of neurons in the primary visual cortex, which are sensitive to the global characteristics of contours, even those that extend well outside their receptive fields.

Contextual influences over large regions of visual space are likely to be mediated by connections between multiple columns of neurons in the visual cortex that have similar orientation selectivity (Figure 27–6B). These connections are formed by pyramidal-cell axons that run parallel to the cortical surface (see Figure 25–16). The extent and orientation dependency of these horizontal connections provide the interactions that could mediate contour saliency (see Figure 25–14).

Figure 27–5 End-inhibited receptive fields. Some receptive fields have a central excitatory region flanked by inhibitory regions that have the same orientation selectivity. Thus a short line segment or a long curved line will activate the neuron (A and C) but a long straight line will not (B). A neuron with a receptive field that displays only one inhibitory region in addition to the excitatory region can signal the presence of corners (D).

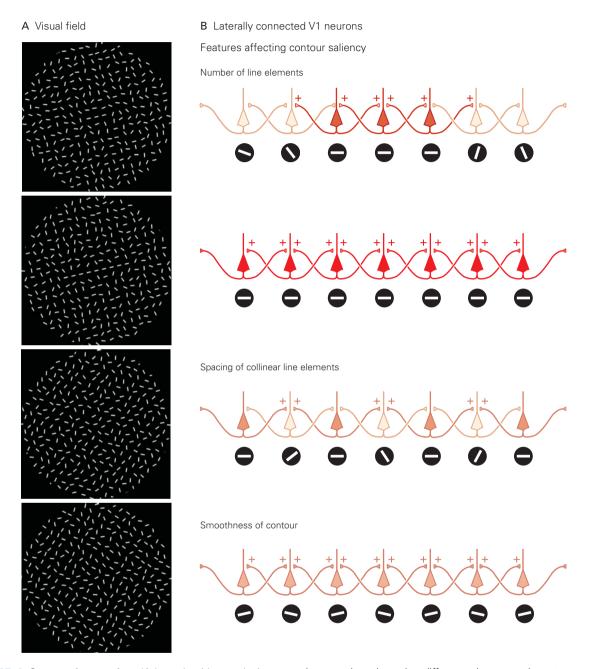

Figure 27–6 Contour integration. (Adapted, with permission, from Li W and Gilbert CD 2002.)

A. Contour integration reflects the perceptual rules of proximity and good continuation. Each of the four images here has a straight line in the center, and all four lines have the same oblique orientation. In some images the line pops out more or less immediately, without searching. Factors that contribute to contour saliency include the number of contour elements (compare the first and second frames), the spacing of the elements (third frame), and the smoothness of the contour (bottom frame). When the spacing between contour elements is too

large or the orientation difference between them too great, one must search the image to find the contour.

B. These perceptual properties are reflected in the horizontal connections that connect columns of neurons in the primary visual cortex with similar orientation selectivity. As long as the contour elements are spaced sufficiently close together, excitation can propagate from cell to cell, thus facilitating the responses of V1 neurons. Each neuron in the network then augments the responses of neurons on either side and the facilitated responses propagate across the network.

Depth Perception Helps Segregate Objects from Background

Depth is another key feature in determining the shape of an object. An important cue for the perception of depth is the difference between the two eyes' views of the world, which must be computed and reconciled by the brain. The integration of binocular input begins in the primary visual cortex, the first level at which individual neurons receive signals from both eyes. The balance of input from the two eyes, a property known as ocular dominance, varies among cells in V1.

These neurons are also selective for depth, which is computed from the relative retinal positions of objects placed at different distances from the observer. An object that lies in the *plane of fixation* produces images at corresponding positions on the two retinas (Figure 27–7). The images of objects that lie in front of or behind the plane of fixation fall on slightly different locations in the two eyes. Individual visual cortex neurons are selective for a narrow range of such disparities. Some are selective for objects lying on the plane of fixation (tuned excitatory or inhibitory cells), whereas others respond only when objects lie in front of the plane of fixation (near cells) or behind that plane (far cells).

Depth plays an important role in the perception of object shape, in surface segmentation, and in establishing the three-dimensional properties of a scene. Objects that are placed near an observer can partially occlude those situated farther away. A surface passing behind an object is perceived as continuous even though its two-dimensional image on each retina represents two surfaces separated by the occluder. When the brain encounters a surface interrupted by gaps displaying appropriate alignment and contrast and lying in the near-depth plane, it fills in the gaps to create a continuous surface (Figure 27–8).

Although the depth of a single object can be established easily, determining the depths of multiple objects within a scene is a much more complex problem that requires linking the retinal images of all objects in the two eyes. The disparity calculation is therefore a global one: The calculation in one part of the visual image influences the calculation for other parts. When the assignment of depth is unambiguous in one part of an image, that information is applied to other parts of the image where there is insufficient information to determine depth, a phenomenon known as disparity capture.

Random-dot stereograms provide a dramatic demonstration of the global nature of disparity analysis. The image presented to each eye appears as noise, but when the images are viewed binocularly the disparity between the random array of dots in the two images

allows an embedded shape to become visible (Figure 27–8C). The calculation underlying this percept is not simple, but requires determining which features shown to the left eye correspond to features seen by the right eye and propagating local disparity information across the image.

Neurons in area V2 display sensitivity to global disparity cues. Even when no contrast boundary exists in a neuron's receptive field, the neuron will respond to illusory contours formed by adjacent line elements (Figure 27–8B). The neuron's response is facilitated when collinear lines appear inside or outside the receptive field. When a perpendicular bar occludes the lines, indicating a break between them, the facilitation disappears. But when the bar is moved to a plane nearer than that of the collinear lines, as would occur if the lines were connected behind the occluder, the facilitation returns.

In addition to binocular disparity, the visual system also uses many monocular cues to discriminate depth. Depth determination through monocular cues, such as size, perspective, occlusion, brightness, and movement, is not difficult. Another cue that originates outside the visual system is vergence, the angle between the optical axes of the two eyes for objects at varying distances. Yet another binocular cue, known as DaVinci stereopsis, is the presence of features visible to one eye but occluded in the other eye's view.

Neurons in areas V1 and V2 also signal foreground-background relationships. A cell with its receptive field in the center of a textured field may respond even when the boundary of that field is distant from the receptive field. This response helps differentiate the object from its background. In parsing an image the brain must identify which edge belongs to which object and differentiate the edge from the background of the object. Some cells in area V2 have the property of "border ownership," firing only when a figure but not the background is to one side of the edge, even when the local edge information is identical in both instances (Figure 27–9).

Local Movement Cues Define Object Trajectory and Shape

The primary visual cortex determines the direction of movement of objects. Directional selectivity in neurons likely involves sequential activation of regions on different sides of the receptive field.

If an object moving at an appropriate velocity first encounters a region of a neuron's receptive field with long response latencies and then passes into regions with progressively shorter latencies, signals from throughout

Plane of fixation

B Disparity-selective neurons

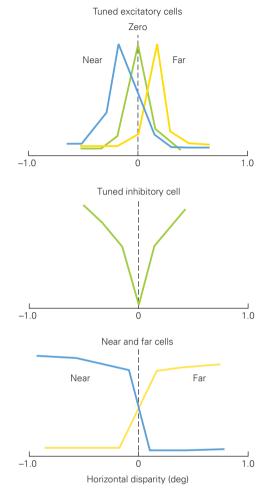

Figure 27–7 Stereopsis and binocular disparity.

A. Depth is computed from the positions at which images occur in the two eyes. The image of an object lying in the plane of fixation (green) falls on corresponding points on the two retinas. The images of objects lying in front of the plane of fixation (blue) or behind it (yellow) fall on noncorresponding locations on the two retinas, a phenomenon termed binocular disparity.

B. Visual cortex neurons are selective for particular ranges of disparity. Each plot shows the responses of a neuron to

binocular stimuli with different disparities (abscissa). Some neurons are tuned to a narrow range of disparities and thus have particular disparity preferences (tuned excitatory or tuned inhibitory neurons), whereas others are tuned broadly for objects in front of the fixation plane (near cells) or beyond the plane (far cells). (Adapted, with permission, from Poggio 1995.)

the receptive field will arrive at the cell simultaneously and the neuron will fire vigorously. If the object instead moves in the opposite direction, signals from the different regions will not summate and the cell may never reach the threshold for firing (Figure 27–10).

Early in the visual pathways analysis of the movement of an object is limited by the size of the receptive fields of the sensory neurons. Even in the initial cortical areas V1 and V2 the receptive fields of neurons

are small and might encompass only a fraction of an object. Eventually, however, information about the direction and speed of movement of discrete aspects of an object must be integrated into a computation of the movement of a whole object. This problem is more difficult than one might expect.

If one observes a complex shape moving through a small aperture, the part of the object's boundary within the aperture appears to move in a direction

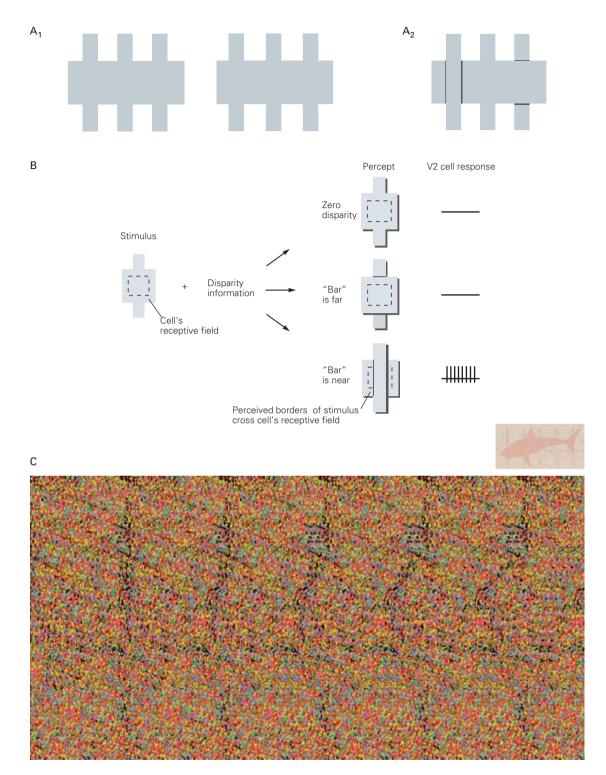

Figure 27–8 Global analysis of binocular disparity.

A. Depth cues contribute to surface segmentation. Viewing a single image of three gray vertical bars crossing a gray horizontal rectangle, you see a uniform gray area within the rectangle. However, if you fuse the two rectangles in A_1 with diverged eyes, the three vertical bars fall on the two retinas with near, zero, and far disparity, respectively, as portrayed in A_2 . Thus the bar at left appears to hover in front of the rectangle with an illusory vertical edge crossing the rectangle, whereas the bar at right appears to lie behind the edges of the horizontal rectangle.

B. A neuron in area V2 responds to illusory edges formed by binocular disparity cues. When the cell's receptive field is centered

in the gray square, the cell does not respond to a vertical bar that has far disparity or the same disparity as the square. When the vertical bar has near disparity, the cell responds as the illusory vertical edge crosses its receptive field. (Reproduced, with permission, from Bakin, Nakayama, and Gilbert 2000.)

C. A random-dot stereogram is seen as a random array of colored dots until one diverges or converges the eyes to bring the adjacent dark vertical stripes into register, producing a three-dimensional image of a shark hovering in front of the background noise. This effect stems from systematic disparity for selected sets of dots. (© Fred Hsu/Wikimedia Commons/ CC-BY-SA-3.0.)

perpendicular to the boundary's orientation (Figure 27–11A). One cannot detect a line's true direction of movement if the line's ends are not visible. The image of a line appears the same if it is moving slowly along an axis perpendicular to its orientation or more quickly along an oblique axis. This is the quandary presented by the receptive field of a V1 neuron. The visual system's solution is to assume that the movement of a contour is perpendicular to its orientation. Thus an object is first presented to the visual system in countless small pieces with boundaries of different orientations, all of which appear to be moving in different directions and at different velocities (Figure 27–11A).

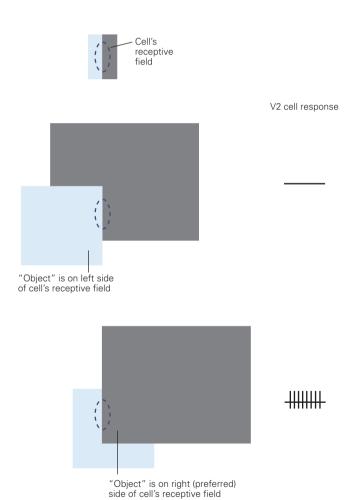

Figure 27–9 Border ownership. Cells in area V2 are sensitive to the boundaries of whole objects. Even though the local contrast is the same for the two rectangles within a cell's receptive field, the cell responds only when the boundary is part of a complete surface that lies on the preferred side of the receptive field. (Adapted, with permission, from Zhou, Friedman, and von der Heydt 2000.)

Determining the direction of motion of an object requires resolving multiple cues. This can be demonstrated readily by placing one grating on top of another and moving the two in different directions. The resulting checkerboard pattern appears to move in an intermediate direction between the trajectories of the individual gratings (Figure 27–11B). This percept depends on the relative contrast of the gratings and the area of grating overlap. With large relative contrasts the gratings appear to slide across each other, moving in their individual directions rather than together in a common direction.

An important determinant of perceived direction is scene segmentation, the separation of moving elements into foreground and background. In a scene with moving objects segmentation is not based on local cues of direction; instead, perception of direction depends on scene segmentation. The barber-pole illusion provides another example of the predominance of global relationships over the perception of simple attributes. The rotating stripes are perceived as moving vertically along the long axis of the pole (Figure 27–11C). The perception of motion in the visual field uses a complex algorithm that integrates the bottom-up analysis of local motion signals with top-down scene segmentation.

Integration of these local motion signals in monkeys has been observed in the middle temporal area (area MT or V5), an area specializing in motion. Remarkably this neural integration mirrors the perceptual effects. The neurons are selective for a particular direction of movement of an overall pattern, rather than to the motion of individual components of the pattern. Their responses also depend on transparency and display the barber-pole effect, sensitivity to the shape and dimensions of the aperture within which the movement is seen.

Context Determines the Perception of Visual Stimuli

Brightness and Color Perception Depend on Context

The visual system attempts to measure the surface characteristics of objects by comparing the light arriving from different parts of the visual field. As a result, the perception of brightness and color is highly dependent on context. In fact, perceived brightness and color can be quite different from what is expected from the physical properties of an object. At the same time, perceptual constancies make objects appear similar even when the brightness and wavelength distribution of

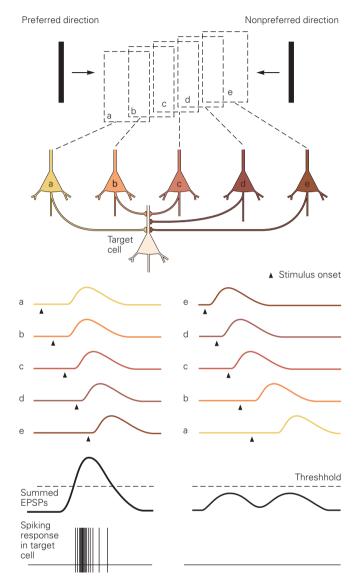

Figure 27–10 Directional selectivity of movement. The selectivity of a neuron to the direction of movement depends on the response latencies of presynaptic neurons. The response latencies of presynaptic neurons *a* and *b* relative to the onset of a stimulus are somewhat longer than those of neurons *d* and *e*. When a stimulus moves from left to right, neurons *a* and then *b* are activated first, but because their responses are delayed their inputs arrive simultaneously with inputs from neurons *d* and *e* and therefore sum at the target neuron, causing it to fire. In contrast, stimuli moving leftward produce responses that arrive at different times and therefore do not reach threshold. (**EPSP**, excitatory postsynaptic potential.) (Adapted, with permission, from Priebe and Ferster 2008.)

the light that illuminates them changes from natural to artificial light, from sunlight to shadow, or from dawn to midday (Figure 27–12A).

As we move about or as the ambient illumination changes, the retinal image of an object—its size, shape, and brightness—also changes. Yet under most conditions we do not perceive the object itself to be changing. As we move from a brightly lit garden into a dimly lit room, the intensity of light reaching the retina may vary a thousandfold. Both in the room's dim illumination and in the sun's glare we nevertheless see a white shirt as white and a red tie as red. Likewise, as a friend walks toward you she is seen as coming closer; you do not perceive her to be growing larger even though the image on your retina does expand. Our ability to perceive an object's size and color as constant illustrates again the fundamental principle of the visual system: It does not record images passively, like a camera, but instead uses transient and variable stimulation of the retina to construct representations of a stable, threedimensional world.

Another example of contextual influence is color induction, whereby the appearance of a color in one region shifts toward that in an adjoining region. Shape also plays an important role in the perception of surface brightness. Because the visual system assumes that illumination comes from above, gray patches on a folded surface appear very different when they lie on the top or bottom of the surface, even when they are in fact the same shade of gray (Figure 27–12B).

The responses of some neurons in the visual cortex correlate with perceived brightness. Most visual neurons respond to surface boundaries; the centersurround structure of the receptive fields of retinal ganglion cells and geniculate neurons is suited to capturing boundaries. Most such cells do not respond to the interior parts of surfaces, for uniform interiors produce no contrast gradients across receptive fields. However, a small percentage of neurons do respond to the interiors of surfaces, signaling local brightness, texture, or color. Their responses are influenced by context: As the brightness of surfaces outside a cell's receptive field change, the cell's response changes, even when the brightness of the surface within the receptive field remains fixed.

Because most neurons respond to surface boundaries and not to areas of uniform brightness, the visual system calculates the brightness of surfaces from information about contrast at the edges of surfaces. The brain's analysis of surface qualities from boundary information is known as perceptual fill-in. If one fixates the boundary between a dark disk and a surrounding bright area for a few seconds, the disk will "fill in" with the same brightness as the surrounding area.

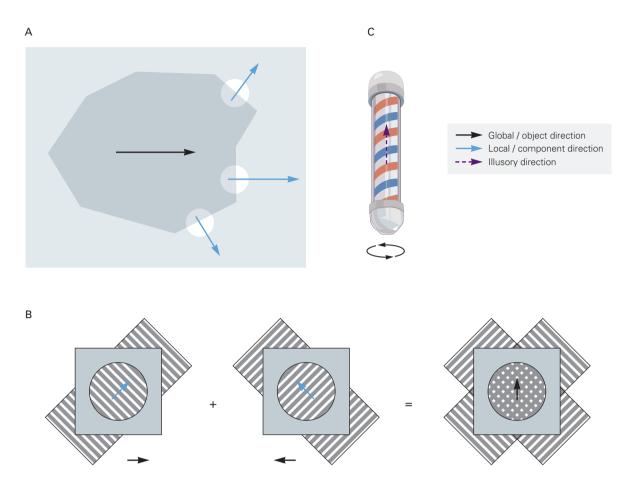

Figure 27–11 The aperture problem and barber-pole illusion.

A. Although an object moves in one direction, each component edge when viewed through a small aperture appears to move in a direction perpendicular to its orientation. The visual system must integrate such local motion signals into a unified percept of a moving object.

B. Gratings are used to test whether a neuron is sensitive to local or global motion signals. When the gratings are superimposed and moved independently in different directions, one

does not see the two gratings sliding past each other but rather a plaid pattern moving in a single, intermediate direction. Neurons in the middle temporal area of monkeys are responsive to such global motion rather than to local motion.

C. Motion perception is influenced by surrounding segmentation cues, as seen in the barber-pole illusion. Even though the pole rotates around its axis, one perceives the stripes as moving vertically.

This occurs because the cells that respond to edges fire only when the eye or stimulus moves. They gradually cease to respond to a stabilized image and no longer signal the presence of the boundary. Neurons with receptive fields within the disk gradually begin to respond in a fashion similar to those with receptive fields in the surrounding area, demonstrating short-term plasticity in their receptive-field properties.

An object's color always appears more or less the same despite the fact that under different conditions of illumination the wavelength distribution of light reflected from the object varies widely. To identify an object we must know the properties of its surface

rather than those of the reflected light, which are constantly changing. Computation of an object's color is therefore more complex than analyzing the spectrum of reflected light. To determine a surface's color the wavelength distribution of the incident light must be determined. In the absence of that information surface color can be estimated by determining the balance of wavelengths coming from different surfaces in a scene. Some neurons in V4 respond similarly to different illumination wavelengths if the perceived color remains constant. By being responsive to the light across an extensive surface, these neurons are selective for surface color rather than wavelength.

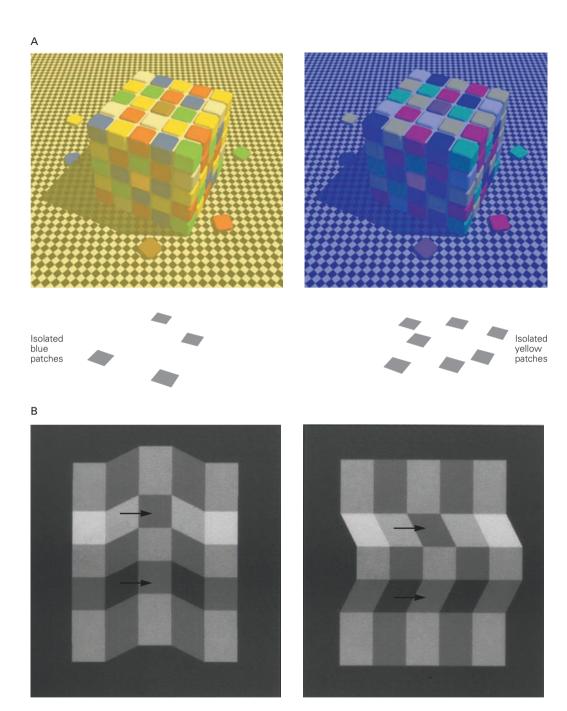

Figure 27–12 Color and brightness perception depend on contextual cues.

A. The perception of surface color remains relatively stable under different illumination conditions and the consequent changes in the wavelengths of light reflected from the surface. The yellow squares on the left and right cubes appear similar despite the fact that the wavelengths of light coming from the two sets of surfaces are very different. In fact, if the blue squares on the top of the left cube and the yellow squares on the top of the right cube are isolated from their contextual squares, their colors appear identical. (Reproduced, with permission, from R. Beau Lotto at www.lottolab.org.)

B. Brightness perception is also influenced by three-dimensional shape. The four gray squares indicated by arrows all have the same luminance. In the left illustration the apparent brightnesses are similar. At the right, however, the apparent brightnesses are different. The visual system has an inherent expectation that illumination comes from above (the position of the sun relative to us), which leads to the perception that the surface below the fold appears brighter than the surface of the same luminance that lies above. (Reproduced, with permission, from Adelson 1993.)

Receptive-Field Properties Depend on Context

The distinction between local and global effects—between stimuli that occur within a receptive field and those beyond—poses the problem of how the receptive field itself is defined. Because the original characterization of the receptive fields of visual cortex neurons did not take into account contextual influences, some investigators now distinguish between "classical" and "nonclassical" receptive fields.

However, even the earliest description of the sensory receptive field allowed for the possibility of influences from portions of the sensory surface outside the narrowly defined receptive field. In 1953 Steven Kuffler, in his pioneering observations on the receptive-field properties of retinal ganglion cells, noted that "not only the areas from which responses can actually be set up by retinal illumination may be included in a definition of the receptive field but also all areas which show a functional connection, by an inhibitory or excitatory effect on a ganglion cell. This may well involve areas which are somewhat remote from a ganglion cell and by themselves do not set up discharges."

A more useful distinction contrasts the response of a neuron to a simple stimulus, such as a short line segment, with its response to a stimulus with multiple components. Even in the primary visual cortex neurons are highly nonlinear; their response to a complex stimulus cannot be predicted from their responses to a simple stimulus placed in different positions around the visual field. Their responses to local features are instead dependent on the global context within which the features are embedded. Contextual influences are pervasive in intermediate-level visual processing, including contour integration, scene segmentation, and the determination of object shape and surface properties.

Cortical Connections, Functional Architecture, and Perception Are Intimately Related

Intermediate-level visual processing requires sharing of information from throughout the visual field. The interconnections within the primary visual cortex and the relationship of these connections to the functional architecture of this area suggest that they mediate contour integration.

Cortical circuits include a plexus of long-range horizontal connections, running parallel to the cortical surface, formed by the axons of pyramidal neurons. Horizontal connections exist in every area of the cerebral cortex, but their function varies from one area to the next depending on the functional architecture of each area. In the visual cortex these connections mediate interactions between orientation columns of similar specificity thus integrating information over a large area of visual cortex that represents a great expanse of the visual field (see Figure 25–14).

The combination of this like-to-like rule of connections and the fact that the horizontal connections link distant locations in the visual field suggest these connections have a role in contour integration. Contour integration and the related property of contour saliency reflect the Gestalt principle of good continuation. Contour integration and saliency are mediated by the horizontal connections in V1 (see Figure 27–6).

A final feature of cortical connectivity important for visuospatial integration is feedback projection from higher-order cortical areas. Feedback connections are as extensive as the feed-forward connections that originate in the thalamus or at earlier stages of cortical processing. Little is known about the function of these feedback projections. They likely play a role in mediating the top-down influences of attention, expectation, and perceptual task, all of which are known to affect early stages in cortical processing.

Perceptual Learning Requires Plasticity in Cortical Connections

The synaptic connections in ocular-dominance columns are adaptable to experience only during a critical period in development (see Chapter 57). This suggests that the functional properties of visual cortex neurons are fixed in adulthood. Nevertheless, many properties of cortical neurons remain mutable throughout life. For example, changes in the visual cortex can occur following retinal lesions.

When focal lesions occur in corresponding positions on the two retinas, the corresponding part of the cortical map, referred to as the lesion projection zone, is initially deprived of visual input. Over a period of several months, however, the receptive fields of cells within this region shift from the lesioned part of the retina to the functioning area surrounding the lesion. As a result, the cortical representation of the lesioned part of the retina shrinks while that of the surrounding region expands (Figure 27–13).

The plasticity of cortical maps and connections did not evolve as a response to lesions. Instead, plasticity is the neural mechanism for improving our perceptual skills. Many of the attributes analyzed by the visual cortex, including stereoscopic acuity, direction of movement, and orientation, become sharper with practice. Hermann von Helmholtz stated in 1866 that

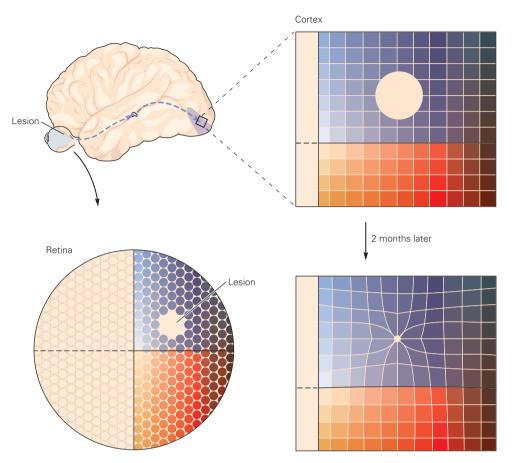

Figure 27-13 Adult cortical plasticity. When corresponding positions in both eyes are lesioned, the cortical area receiving input from the lesioned areas—the lesion projection zone—is initially silenced. The receptive fields of neurons in the lesion projection zone eventually shift from the area of the lesion to

the surrounding, intact retina. This occurs because neurons surrounding the lesion projection zone sprout collaterals that form synaptic connections with neurons inside the zone. As a result, the cortical representation of the lesioned part of the retina shrinks while that of the surrounding retina expands.

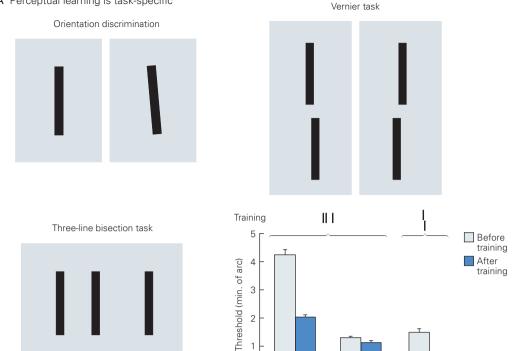

"the judgment of the senses may be modified by experience and by training derived under various circumstances, and may be adapted to the new conditions. Thus, persons may learn in some measure to utilize details of the sensation which otherwise would escape notice and not contribute to obtaining any idea of the object." This perceptual learning is a variety of implicit learning that does not involve conscious processes (see Chapter 65).

Perceptual learning involves repeating a discrimination task many times and does not require error feedback to improve performance. Improvement manifests itself as a decrease in the threshold for discriminating small differences in the attributes of a target stimulus or in the ability to detect a target in a complex environment. Several areas of visual cortex, including the primary visual cortex, participate in perceptual learning.

An important aspect of perceptual learning is its specificity: Training on one task does not transfer to other tasks. For example, in a three-line bisection task the subject must determine whether the centermost of three parallel lines is closer to the line on the left or the one on the right. The amount of offset from the central position required for accurate responses decreases substantially after repeated practice (Figure 27–14A).

The learning in this task is specific to the location in the visual field and to the orientation of the lines. This specificity suggests that early stages of visual processing are responsible, for in the early stages receptive fields are smallest, visuotopic maps are most precise, and orientation tuning is sharpest. The learning is also

A Perceptual learning is task-specific

0

Performance | | Task

Task

B Neuronal responsiveness changes during training

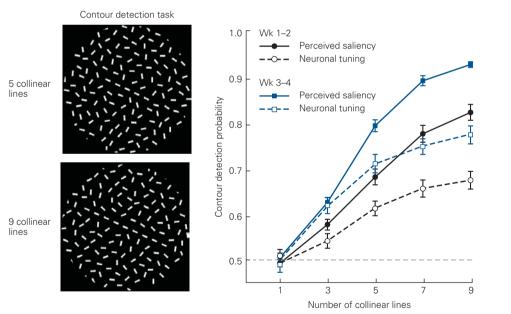

Figure 27–14 Perceptual learning. Perceptual learning is a form of implicit learning. With practice one can learn to discriminate smaller differences in orientation, position, depth, and direction of movement of objects.

A. The improvement is seen as a reduction in the amount of change required to reliably detect a tilted line or one positioned to the left or right of a nearly collinear line (vernier task). Perceptual learning is highly specific, so that training on a three-line bisection task leads to substantial improvement in that task (left pair of bars in the bar graph) without affecting performance on the vernier discrimination task (central pair of bars).

However, training specifically on vernier discrimination does enhance performance on that task (right pair of bars).

B. The responses of neurons in V1 parallel perceptual learning. Subjects can detect collinear line segments embedded in a random background more easily as the number of segments is increased. The responses of neurons in V1 grow correspondingly stronger with the increase in the number of line segments. After practice, a line with fewer segments stands out more easily, and with this improvement the responses in V1 also increase. (Reproduced, with permission, from Crist et al. 2001; and Li et al. 2008.)

specific for the stimulus configuration. Training on three-line bisection does not transfer to a vernier discrimination task in which the context is a line that is collinear with the target line (see Figure 27–14A).

The response properties of neurons in the primary visual cortex change during the course of perceptual learning in a way that tracks the perceptual improvement. An example of this is seen in contour saliency. With practice, subjects can more easily detect contours embedded in complex backgrounds. Detection improves with contour length, and the responses of neurons in V1 increase as well. With practice, subjects improve their ability to detect shorter contours and V1 neurons become correspondingly more sensitive to shorter contours (see Figure 27–14B).

Visual Search Relies on the Cortical Representation of Visual Attributes and Shapes

The detectability of features such as color, orientation, and shape is related to the process of visual search. Certain objects emerge or "pop out" from others in a complex image because the visual system processes

simultaneously, in parallel pathways, the features of the target and the surrounding distractors (Figure 27–15). When the features of a target are complex, the target can be identified only through careful inspection of an entire image or scene (see Figure 21–5).

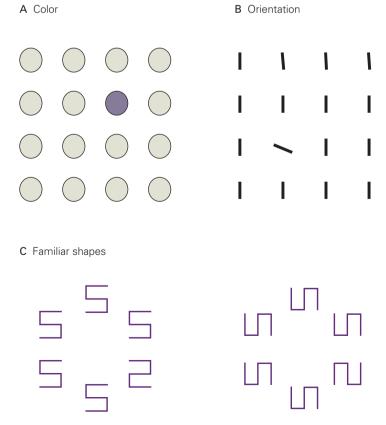

The pop-out phenomenon can be influenced by training. A stimulus that initially cannot be found without effortful searching will pop out after training. The neuronal correlate of such a dramatic change is not certain. Parallel processing of the features of an object and its background is possible because feature information is encoded within retinotopically mapped areas at multiple locations in the visual cortex. Pop-out probably occurs early in the visual cortex. The pop-out of complex shapes such as numerals lends support to the idea that early in visual processing neurons can represent, and be selective for, shapes more complex than line segments with a particular orientation.

Cognitive Processes Influence Visual Perception

Scene segmentation—the parsing of a scene into different objects—involves a combination of bottom-up

- A. A differently colored object pops out.
- B. A differently oriented line also pops out.
- C. More complex shapes can pop out when they are very familiar, such as the numeral 2 embedded in a field of 5s. Rotating the image by 90° renders the elements of the figure less recognizable, making it more difficult to find the one figure that differs from the rest. (Reproduced, with permission, from Wang, Cavanagh, and Green 1994.)

processes that follow the Gestalt rule of good continuation and top-down processes that create object expectation.

One strong top-down influence is spatial attention, which can change focus without any movement of an observer's eyes. Spatial attention is object-oriented in that it is distributed over the area occupied by the attended object, allowing the visual cortex to analyze the shape and attributes of objects one at a time.

Attentional mechanisms can solve the superposition problem. For us to recognize an object in a scene that includes multiple objects, we must determine which features correspond to which objects. Our sense that we identify multiple objects simultaneously is illusory. Instead, we serially process objects in rapid succession by shifting attention from one to the next. The results of each analysis build up the perception of a complex environment populated with many distinct objects. A dramatic demonstration of the importance of attention in object recognition is *change blindness*. If a subject rapidly shifts between two slightly different views of the same scene, he will not be able to detect the absence of an important component of the scene in one view without considerable scrutiny (see Figure 29–3).

Another top-down influence is perceptual task. At early stages in visual processing the properties of the same neuron vary with the type of visual discrimination being performed. Object identification itself involves a process of hypothesis testing in which internal representations of objects are compared with information arriving from the retina. This process is reflected in studies of visual imagery: Early stages in processing such as the primary visual cortex are activated when one imagines scenes in the absence of visual input.

An Overall View

Intermediate-level visual processing is concerned with parsing the visual world into contours and surfaces that belong to objects and segregating these elements from the background. This is the most challenging job that the visual system must perform. When confronted with a complex visual environment, we could assemble local features into a potentially enormous number of distinct objects. Nonetheless, we quickly classify the local features into a set of objects that can be matched with internal representations of object shape and identity that are stored in the brain from earlier experiences.

This global integration is simplified by applying rules of perceptual grouping that were described by Gestalt psychologists and are apparently implemented by circuits beginning in the primary visual cortex. Global integration involves analysis of local attributes that depends on the properties of sensory neurons: Selectivity for local orientation supports the analysis of extended contours, directional sensitivity underlies the determination of object motion, disparity selectivity implements global stereopsis, and contrast sensitivity mediates color constancy. The process of integration is not simply a bottom-up one but is influenced by information arriving from higher-order areas of the visual cortex. Attention, expectation, and perceptual task influence how we segment the visual world.

Intermediate-level vision is a product of lateral connections between functional columns of neurons in a cortical area and the convergence of feed-forward signals with feedback information from higher-order areas. Vision therefore is not simply a feed-forward mechanism that assembles shapes in stages with increasing complexity. The underlying processes are highly dynamic on short time scales. The strategies that we use to interpret visual scenes also involve experience-dependent changes in the cortical circuits in which we constantly store information about shapes that we experience throughout life.

THE IMAGES PROJECTED ONTO THE retina are generally complex dynamic patterns of light of varying intensity and color. As we have seen, low-level visual processing is responsible for detection of various types of contrast in these images (see

Chapters 25 and 26), whereas intermediate-level processing is involved in the identification of so-called visual primitives, such as contours and fields of motion, and the representation of surfaces (see Chapter 27). High-level visual processing integrates information from a variety of sources and is the final stage in the visual pathway leading to conscious visual experience.

In practice high-level visual processing depends on top-down signals that imbue bottom-up (afferent) sensory representations with semantic significance, such as that arising from short-term working memory, long-term memory, and behavioral goals. High-level visual processing thus selects behaviorally meaningful attributes of the visual environment (Figure 28–1).

High-Level Visual Processing Is Concerned with Object Identification

Our visual experience of the world is fundamentally object-centered. Objects are often visually complex, being composed of a large number of conjoined visual features. In addition, the features projected on the retina by an object vary greatly under different viewing conditions, such as lighting, angle, position, and distance.

Moreover, objects are commonly associated with specific experiences, other remembered objects, other sensations—such as the hum of the coffee grinder or the aroma of a lover's perfume—and a variety of emotions. Animate beings, which are objects to the visual

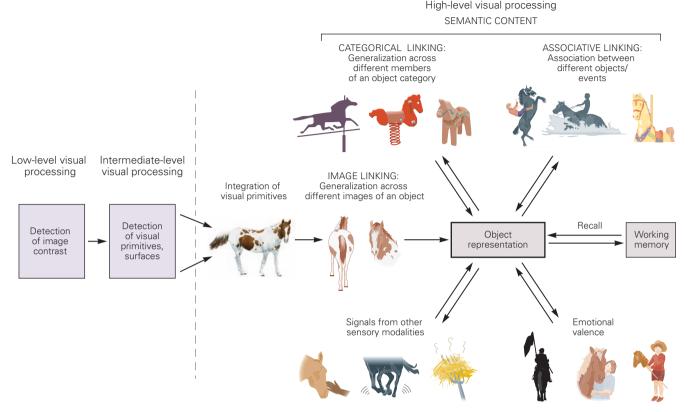

Figure 28–1 The neuronal representation of entire objects is central to high-level visual processing. Object representation involves integration of visual features extracted at earlier stages in the visual pathways. Ideally the resulting representation is a generalization of the numerous retinal images generated by the same object and of different members of an object category.

The representation also incorporates information from other sensory modalities, attaches emotional valence, and associates the object with the memory of other objects or events. Object representations can be stored in working memory and recalled in association with other memories.

system, also direct intentions, desires, and actions at others and ourselves. In conjunction with our own behavioral goals, it is the behavioral saliency of individual objects, memories, and emotional valences as well as the real or implied actions of others that enables us to take action based on visual information. Object perception is thus the nexus between vision and cognition.

The Inferior Temporal Cortex Is the Primary Center for Object Perception

Primate studies implicate neocortical regions of the temporal lobe, principally the inferior temporal cortex, in object perception. Because the hierarchy of synaptic relays in the cortical visual system extends from the primary visual cortex to the temporal lobe, the temporal lobe is a site of convergence of many types of visual information.

As we shall later see, neuropsychological studies have found that damage to the inferior temporal cortex can produce specific failures of object recognition. Neurophysiological and brain-imaging studies have in turn yielded remarkable insights into the ways in which the activity of inferior temporal neurons represents objects, how these representations relate to perceptual and cognitive events, and how they are modified by experience.

Visual signals originating in the retina are processed in the lateral geniculate nucleus of the thalamus before reaching the primary visual cortex (V1). Thereafter ascending visual pathways follow two parallel and hierarchically organized streams: the ventral and dorsal streams (see Chapter 25). The ventral stream extends ventrally and anteriorly from V1 through

V2, V4, and the temporal-occipital junction before reaching the inferior temporal cortex, which comprises the lower bank of the superior temporal sulcus and the ventrolateral convexity of the temporal lobe (Figure 28–2). This pathway makes the inferior temporal cortex the seat of the highest stage of cortical visual processing. Neurons at each synaptic relay in this ventral stream receive convergent input from the preceding stage. Inferior temporal neurons are thus in a position to

integrate a large and diverse quantity of visual information over a vast region of visual space.

The inferior temporal cortex is a large brain region. The patterns of anatomical connections to and from this area indicate that it comprises at least two main functional subdivisions: the posterior and anterior inferior temporal cortex. Anatomical evidence identifies the anterior subdivision as a higher processing stage than the posterior subdivision. As we shall see,

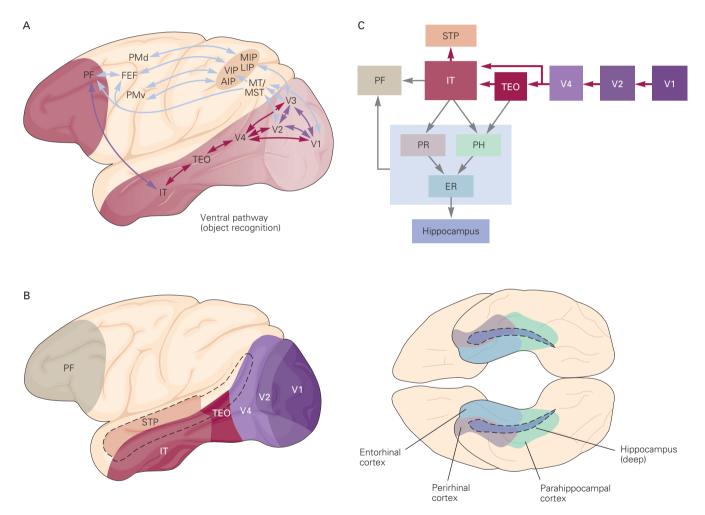

Figure 28-2 Cortical pathway for object recognition.

A. The pathway for object recognition (red) is identified in a lateral view of the brain showing the major pathways involved in visual processing. (AIP, anterior intraparietal cortex; FEF, frontal eye fields; IT, inferior temporal cortex; LIP, lateral intraparietal cortex; MIP, medial intraparietal cortex; MST, medial superior temporal cortex; MT, middle temporal cortex; PF, prefrontal cortex; PMd, dorsal premotor cortex; PMv, ventral premotor cortex; TEO, temporo-occipital cortex; VIP, ventral intraparietal cortex.)

B. Cortical areas involved in object recognition are shown on lateral and ventral views of the monkey brain.

C. The inferior temporal cortex (IT) is the end stage of the ventral stream (red arrows), and is reciprocally connected with neighboring areas of the medial temporal lobe and prefrontal cortex (gray arrows). This chart illustrates the main connections and predominant direction of information flow. (ER, entorhinal cortex; PF, prefrontal cortex; PH, parahippocampal cortex; PR, perirhinal cortex; STP, superior temporal polysensory area; TEO, temporo-occipital cortex.)

this distinction is supported by both neuropsychological and neurophysiological evidence.

Clinical Evidence Identifies the Inferior Temporal Cortex as Essential for Object Recognition

The first clear insight into the neural pathways mediating object recognition was obtained in the late 19th century when the American neurologist Sanger Brown and the British physiologist Edward Albert Schäfer found that experimental lesions of the temporal lobe in primates resulted in loss of the ability to recognize objects. This impairment is distinct from the deficits that accompany lesions of occipital cortical areas in that sensitivity to basic visual attributes, such as color, motion, and distance, remains intact. Because of the unusual type of visual loss, the impairment was originally called psychic blindness, but this term was later replaced by *visual agnosia* ("without visual knowledge"), a term coined by Sigmund Freud.

In humans there are two basic categories of visual agnosia, apperceptive and associative, the description of which led to a two-stage model of object recognition in the visual system (Figure 28–3). With apperceptive agnosia the ability to match or copy complex visual shapes or objects is impaired. This impairment is perceptual in nature, resulting from disruption of the first stage of object recognition: integration of visual features into sensory representations of entire objects. In contrast, patients with associative agnosia can match or copy complex objects, but their ability to identify the objects is impaired. This impairment results from disruption of the second stage of object recognition: association of the sensory representation of an object with knowledge of the object's meaning or function.

Consistent with this functional hierarchy, apperceptive agnosia is most common following damage to the posterior inferior temporal cortex, whereas associative agnosia, a higher-order perceptual deficit, is more common following damage to the anterior inferior temporal cortex, a later stage in the functional hierarchy. Neurons in the anterior subdivision exhibit a variety of memory-related properties not seen in the posterior area.

Neurons in the Inferior Temporal Cortex Encode Complex Visual Stimuli

The coding of visual information in the temporal lobe has been studied extensively using electrophysiological techniques, beginning with the work of Charles Gross and colleagues in the 1970s. Neurons in this region have distinctive response properties. They are relatively insensitive to simple stimulus features such as orientation and color. Instead, the vast majority possess large, centrally located receptive fields and encode complex stimulus features. These selectivities often appear somewhat arbitrary. An individual neuron might, for example, respond strongly to a crescent-shaped pattern of a particular color and texture. Cells with such unique selectivities likely provide inputs to yet higher-order neuronal representations of meaningful objects.

Indeed, several small subpopulations of neurons encode objects that convey to the observer highly meaningful information, such as faces and hands (Figure 28–4). For cells that respond to the sight of a hand, individual fingers are particularly critical. Among cells that respond to faces, the most effective stimulus for some cells is the frontal view of the face, whereas for others it is the side view. Although some neurons respond preferentially to faces, others respond to facial expressions. It seems likely that such cells contribute directly to face recognition.

Damage to a small region of the human temporal lobe results in an inability to recognize faces, a form of associative agnosia known as *prosopagnosia*. Patients with prosopagnosia can identify a face as a face, recognize its parts, and even detect specific emotions expressed by the face, but they are unable to identify a particular face as belonging to a specific person.

Prosopagnosia is one example of "category-specific" agnosia, in which patients with temporal-lobe damage fail to recognize items within a specific semantic category. There are reported cases of category-specific agnosias for living things, fruits, vegetables, tools, or animals. Owing to the pronounced behavioral significance of faces and the normal ability of people to recognize an extraordinarily large number of items from this category, prosopagnosia may simply be the most common variety of category-specific agnosia.

Neurons in the Inferior Temporal Cortex Are Functionally Organized in Columns

Early relays in the cortical visual system are organized in columns of neurons that represent the same stimulus features, such as orientation or direction of motion, in different parts of the visual field. Cells within the inferior temporal cortex are also organized in columns of neurons representing the same or similar stimulus properties (Figure 28–5). These columns commonly extend throughout the cortical thickness and over a range of approximately 400 μ m. Columnar patches in the inferior temporal cortex are arranged such that different stimuli that possess some similar features are

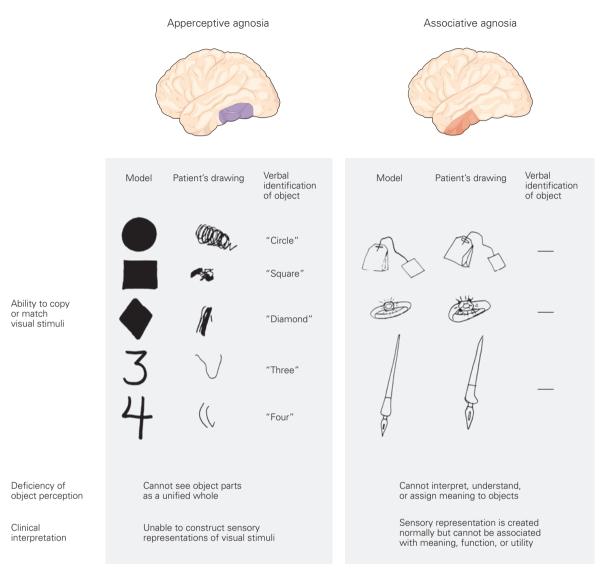

Figure 28–3 Neuropsychological evidence for the neuronal correlates of object recognition in the temporal lobe. Damage to inferior temporal cortex (IT) impairs the ability to recognize visual objects, a condition known as visual agnosia.

There are two major categories of visual agnosia: apperceptive, a result of damage to the posterior region, and associative, resulting from damage of the anterior region. (Reproduced, with permission, from Farah 1990.)

represented in partially overlapping columns (Figure 28–5). Thus one stimulus can activate multiple patches within the cortex. Long-range horizontal connections within the cortex may serve to connect patches into distributed networks for object representation.

Face-selective cells constitute a highly specialized class of neurons. Indeed, the fact that prosopagnosia often occurs in the absence of any other form of agnosia suggests that face-selective neurons of the temporal lobe may be located in exclusive clusters. While many early studies of neuronal response properties offered circumstantial evidence for such clustering, in

2006 Doris Tsao and Margaret Livingstone obtained dramatic support for this hypothesis. Functional magnetic resonance images of monkeys that were viewing faces revealed large active zones in a region of cortex in the lower bank of the superior temporal sulcus. Neurophysiological recordings of neurons in these zones confirmed that face-recognition cells formed large, dense clusters (Figure 28–6). Winrich Freiwald and Tsao later found that the five face-representation areas in monkeys interconnect with one another and form a processing system, with each node apparently concerned with a different aspect of face recognition.

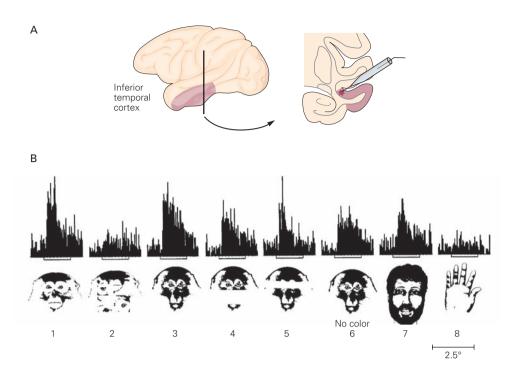

Figure 28–4 Neurons in the inferior temporal cortex of the monkey are involved in face recognition. (Reproduced, with permission, from Desimone et al. 1984.)

A. The location of the inferior temporal cortex of the monkey is shown in a lateral view and coronal section. The colored area is the location of the recorded neurons.

B. Peristimulus histograms illustrate the frequency of action potentials in a single neuron in response to the different images illustrated below. This neuron responded selectively to faces. Masking of critical features, such as the mouth or eyes (4, 5), led to a substantial but not complete reduction in response. Scrambling the parts of the face (2) nearly eliminated the response.

The Inferior Temporal Cortex Is Part of a Network of Cortical Areas Involved in Object Recognition

Object recognition is intimately intertwined with visual categorization, visual memory, and emotion, and the outputs of the inferior temporal cortex contribute to these functions (see Figure 28–2).

Among the principal projections are those to the perirhinal and parahippocampal cortices, which lie medially adjacent to the ventral surface of the inferior temporal cortex (see Figure 28–2C). These regions project in turn to the entorhinal cortex and the hippocampal formation, both of which are involved in long-term memory storage and retrieval. A second major projection from the inferior temporal cortex is to the prefrontal cortex, which is increasingly recognized as an important contributor to high-level vision. As we shall see, prefrontal neurons play important roles in categorical visual perception, visual working memory, and recall of stored memories.

The inferior temporal cortex also provides input—directly and indirectly via the perirhinal cortex—to the amygdala, which is believed to apply emotional

valence to sensory stimuli and to engage the cognitive and visceral components of emotion (see Chapter 48). Finally, the inferior temporal cortex is a major source of input to multimodal sensory areas of cortex such as the superior temporal polysensory area.

Object Recognition Relies on Perceptual Constancy

The ability to recognize objects as the same under different viewing conditions, despite the sometimes markedly different retinal images, is one of the most functionally important requirements of visual experience. The invariant attributes of an object—for example, the spatial and chromatic relationships between image features or characteristic features such as the stripes of a zebra—are cues to the identity and meaning of the objects.

For object recognition to take place, these invariant attributes must be represented independently of other image properties. The visual system does this with proficiency, and its behavioral manifestation is

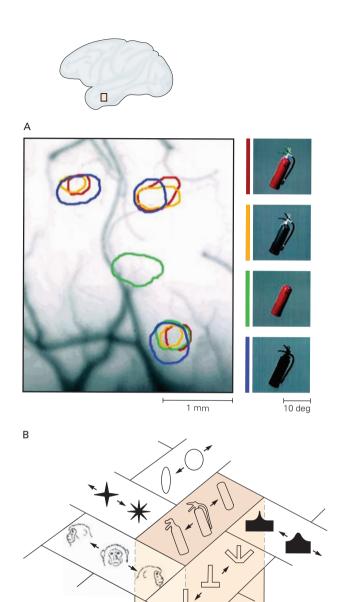

Figure 28–5 Neurons in the anterior portion of the inferior temporal cortex that represent complex visual stimuli are organized into columns. (Reproduced, with permission, from Tanaka 2003.)

A. Optical images of the surface of the anterior inferior temporal cortex illustrate regions selectively activated by the objects shown at the right.

B. In this schematic depiction of the columnar structure of the inferior temporal cortex the vertical axis represents cortical depth. According to this model each column includes neurons that represent a distinct complex pattern. Columns of neurons that represent variations of a pattern, such as the different faces or the different fire extinguishers, constitute a hypercolumn.

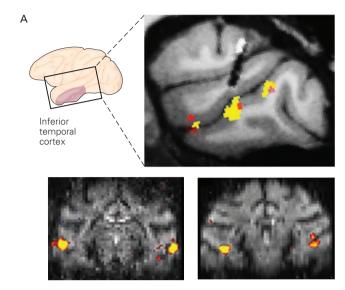

termed *perceptual constancy*. Perceptual constancy has many forms ranging from invariance across simple transformations of an object, such as size, position, and rotation, to the sameness of objects within a common category: All zebras look alike.

One of the best examples is *size constancy*. An object placed at different distances from an observer is perceived as having the same size, even though the object produces images of different absolute size on the retina. Size constancy has been recognized for centuries, but only in the past several decades has it been possible to identify the neural mechanisms responsible. An early study found that lesions of the inferior temporal cortex lead to failures of size constancy in monkeys, suggesting that neurons in this area play a critical role in size constancy. Indeed, one of the most striking and best-documented features of the response properties of individual inferior temporal neurons is the invariance of their pattern of selective responses to changes in stimulus size (Figure 28–7A).

Another relatively simple type of perceptual constancy is *position constancy*, in which objects are recognized as the same regardless of their location in the visual field. The pattern of selective responses of many inferior temporal neurons does not vary when the position of an object within their large receptive fields is changed (Figure 28–7B). *Form-cue invariance* refers to the constancy of a form when the cues that define the form change. The silhouette of Abraham Lincoln's head, for example, is readily recognizable whether it is black on white, white on black, or red on green. The responses of many inferior temporal neurons do not change with changes in contrast polarity (Figure 28–7C), color, or texture.

Viewpoint invariance refers to the perceptual constancy of three-dimensional objects observed from different angles. Despite the limitless range of retinal images that might be cast by a familiar object, an observer can readily recognize the object independently of the angle at which it is viewed. There are notable exceptions to this rule, which generally occur when an object is viewed from an angle that yields an uncharacteristic retinal image, such as a bucket viewed from directly above.

Investigators have looked for neurons whose response properties would account for viewpoint invariance but have found surprisingly little evidence. On the contrary, most neurons are tuned for specific viewing angles of a three-dimensional object. Although this tuning is often broad, thus reflecting partial viewpoint invariance, it appears that individual neurons do not generalize across inputs sufficiently to account for viewpoint invariance. Another possibility is that viewpoint invariance is the product of population coding by an ensemble of neurons each tuned to a different viewing angle. Finally, viewpoint invariance may be

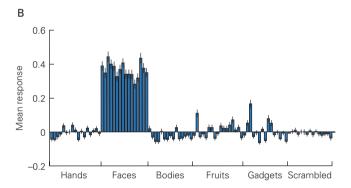

Figure 28–6 The inferior temporal cortex contains dense clusters of face-selective neurons. (Reproduced, with permission, from Tsao et al. 2006.)

A. Functional magnetic resonance imaging (fMRI) identifies three regions of the inferior temporal cortex that are selectively activated by faces. The upper image, a sagittal section, shows the three active zones along the lower bank of the superior temporal sulcus in one monkey. The two lower images are coronal sections through the face-representation areas in two monkeys.

B. Neurophysiological recordings reveal a preponderance of face-selective neurons in the middle face area identified by fMRI. The histogram plots the mean normalized response rate (minus baseline) of 182 neurons in the middle face area of one monkey. The monkey was shown 96 visual stimuli in six categories. Only faces elicited consistently vigorous responses.

achieved at a higher stage of cortical processing, such as the prefrontal cortex, through convergent inputs from neurons selective for specific viewpoints.

Studies of the conditions under which viewpoint invariance fails may lead to insights into the neural mechanisms of the behavior. One such condition is presentation of mirror images. Although mirror images are not identical, they are frequently perceived as the same, a confusion reflecting a false-positive identification by the system for viewpoint invariance. Carl Olson and colleagues examined the responses of neurons in the inferior temporal cortex to stimuli that were mirror images. Consistent with the perceptual confusion, many inferior temporal neurons responded similarly to both images. This result reinforces the conclusion that activity in the inferior temporal cortex reflects perceptual invariance, albeit incorrectly in this case, rather than the actual sensory information.

Categorical Perception of Objects Simplifies Behavior

All forms of perceptual constancy are the product of the visual system's attempts to generalize across different retinal images generated by a single object. A still more general type of constancy is the perception of individual objects as belonging to the same semantic category. The apples in a basket or the many appearances of the letter *A*, for example, are physically distinct but are effortlessly perceived as *categorically* identical under many behavioral conditions.

Categorical perception is classically defined by the ability to distinguish objects of different categories even when objects of the same category cannot be distinguished. For example, it is more difficult to discriminate between two red lights that differ in wavelength by 10 nm than to discriminate between red and orange lights with the same wavelength difference.

Categorical perception simplifies behavior. For example, it usually does not matter whether an apple is completely spherical or slightly mottled on the left side, or whether the seat we are offered is a Windsor or a Chippendale side chair. Similarly, reading ability requires that one be able to recognize the alphabet in a broad variety of type styles. Like the simpler forms of perceptual constancy, categorical perception reflects sensitivity to invariant visual attributes.

Is there a population of neurons that respond uniformly to objects within a category and differentially to objects of different categories? To test this Earl Miller and colleagues created a set of images in which features of dogs and cats were merged; the proportions of dog and cat in the composite images varied continuously from one extreme to the other. Monkeys were trained to identify these stimuli reliably as either dog or cat. Miller and colleagues then recorded from visually responsive neurons in the lateral prefrontal cortex, a region that receives direct input from the inferior

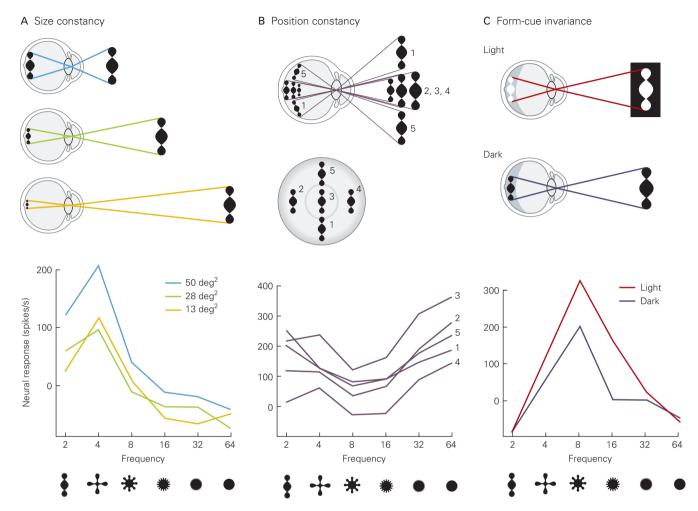

Figure 28–7 Perpetual constancy is reflected in the behavior of neurons in the inferior temporal cortex. The responses of many inferior temporal neurons are selective for stimuli with particular numbers or frequencies of lobes but invariant with regard to object size, position, and reflectance. (Reproduced, with permission, from Schwartz et al. 1983.)

A. Size constancy. An object is perceived to be the same even when the retinal image size decreases with the distance of the object in the visual field. The response of the vast majority of inferior temporal neurons to substantial changes in retinal image size is invariant, as illustrated here by the record of a single cell.

B. Position constancy. An object is perceived to be the same despite changes in position in the retinal image. Almost all inferior temporal neurons respond similarly to the same stimulus in different positions in the visual field, as illustrated here by the record of a single neuron.

C. Form-cue invariance. An object is perceived to be the same despite changes in reflectance. Most inferior temporal neurons respond similarly to the two viewing conditions illustrated, as shown in the record of the individual neuron.

temporal cortex. Not only did these neurons exhibit the predicted category-specific responses—responding well to cat but not dog, or *vice versa*—but the neuronal category boundary also corresponded to the behaviorally learned category boundary (Figure 28–8).

The fact that category-specific agnosias sometimes follow damage to the temporal lobe suggests there are neurons in the inferior temporal cortex that have category-specific responses similar to those of neurons in the prefrontal cortex. Face-recognition cells appear to meet this criterion, for their responses to a range of faces are often similar. Face-recognition cells may constitute a special case, however, for learned category-specific responses of the sort tested by Miller in the prefrontal cortex are rarely seen in the inferior temporal cortex. For most stimulus conditions category-specific

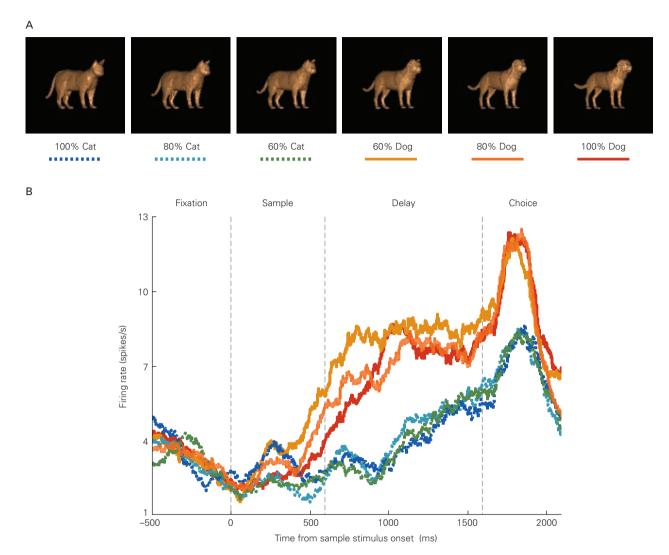

Figure 28–8 Neural coding for categorical perception. (Reproduced, with permission, from Freedman et al. 2002.)

A. The images combine cat and dog features in varying proportions. Monkeys were trained to identify an image as cat or dog if it had 50% or more features of that animal.

B. Peristimulus histograms illustrate the responses of a prefrontal cortex neuron to the images shown in part A. The

neuron was selectively responsive to images of dogs. Despite the different retinal images, the responses to images within each category (dog or cat) are similar. By contrast, the responses to images in different categories (cat *versus* dog) differ significantly. Category-specific responses are common among visual neurons of the prefrontal cortex.

representations may be generated in the prefrontal cortex, where visual responses are more commonly linked to the behavioral significance of the stimuli.

Visual Memory Is a Component of High-Level Visual Processing

Visual experience can be stored as memory, and visual memory influences the processing of incoming visual

information. Object recognition, in particular, relies on the observer's previous experiences with objects. Thus the contributions of the inferior temporal cortex to object recognition must be modifiable by experience.

Studies of the role of experience in visual perception have focused on two distinct types of experience-dependent plasticity in the visual system. One stems from repeated exposure or practice, which leads to improvements in visual discrimination and object-recognition ability. These experience-dependent changes

constitute a form of implicit learning known as perceptual learning (see Chapter 27). The other occurs in connection with the storage of explicit learning, the learning of facts or events that can be recalled consciously (see Chapter 67).

Implicit Visual Learning Leads to Changes in the Selectivity of Neuronal Responses

The ability to resolve differences between complex visual stimuli is highly modifiable by experience. For example, individuals who attend to and examine fine differences between different models of automobiles or eyeglasses become far better at discriminating and recognizing such differences.

In the inferior temporal cortex neuronal selectivity for complex objects can undergo change that parallels changes in the ability to distinguish objects. For example, in one study monkeys were trained to identify novel three-dimensional objects, such as randomly bent wire forms, from two-dimensional views of the objects. Extensive training led to pronounced improvements in the ability to recognize the objects from two-dimensional views. Extracellular recordings from the inferior temporal cortex after training revealed a population of neurons that exhibited marked selectivity for the views seen earlier but not for other two-dimensional views of the same objects (Figure 28–9).

Other studies with monkeys have shown that familiarity with novel faces alters the tuning of many face-selective neurons in the inferior temporal cortex. Similarly, when an animal has experience with novel objects formed from simple features, inferior-temporal neurons become selective for those objects. Such neuronal changes can result from either active discrimination or passive viewing and are often manifested as a sharpening of stimulus selectivity rather than changes in absolute firing rate. Sharpening is precisely the sort of neuronal change that could underlie improvements in perceptual discrimination of visual stimuli.

Explicit Visual Learning Depends on Linkage of the Visual System and Declarative Memory Formation

Progress has been made in understanding the neurobiology of interaction between vision and memory, specifically in relation to two issues. First, how is visual sensory information maintained in short-term working memory? Working memory has a limited capacity, acting like a buffer in a computer operating system, and is susceptible to interference as when trying to remember the face of a person you have just met. Second, how are long-term visual memories and the associations between them stored and recalled?

Visual neurons in both the inferior temporal and prefrontal cortices continue firing during the delay in a visual delayed-response task (Box 28–1).

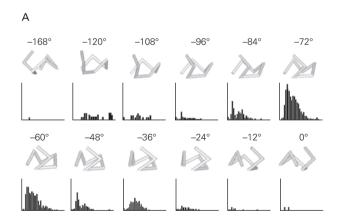

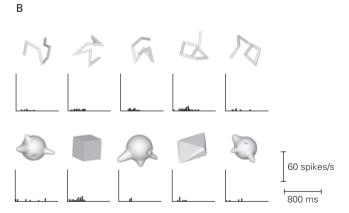

Figure 28–9 Familiarity with particular complex objects leads inferior temporal neurons to respond selectively for those objects. (Reproduced, with permission, from Logothetis and Pauls 1995.)

A. Monkeys were trained to recognize a randomly bent wire from a set of two-dimensional views of the wire. The wire form was rotated 12 degrees in each successive view. Once performance was stable at a high level, extracellular recordings

were made from neurons in the inferior temporal cortex while each view was presented. The responses of a typical neuron to each view are plotted in the form of peristimulus histograms. This neuron responded selectively to views that represented a small range of rotation of the object.

B. The same neuron was tested with two sets of "distractor" stimuli that were unfamiliar to the monkey. It failed to respond to any of these stimuli.

Box 28–1 Investigating Interactions Between Vision and Memory

The relationship between vision and memory can be studied by combining a neuropsychological approach with single-cell electrophysiological methods.

One behavioral paradigm used to study memory is the *delayed-response task*. An animal is required to make a specific response based on information remembered during a brief delay. In one form of this task, known as *delayed match-to-sample*, the subject must indicate whether a visual stimulus is the same or different from a previously viewed sample (Figure 28–10A).

For example, the subject is shown a photograph of a tractor and then, after a brief delay, is shown several photographs of tractors, only one of which is identical to the sample tractor previously viewed. The task is to identify the tractor that matches the sample.

When used in conjunction with single-cell recording, this task allows the experimenter to isolate three key components of a neuronal response: (1) the sensory component, the response elicited by the sample stimulus;

(2) the short-term or working-memory component, the response that occurs during the delay between the sample and the match; and (3) the recognition-memory or familiarity component, the difference between the response elicited by the match stimulus and the earlier response to the sample stimulus.

A second behavioral paradigm, known as the *visual paired-association task*, has been used in conjunction with electrophysiology to explore the cellular mechanisms underlying the long-term storage and recall of associations between visual stimuli (Figure 28–10B).

This task differs from the delayed match-to-sample task in that the match and sample are two different stimuli. The sample stimulus might consist of the letter A and the match stimulus the letter B. Through repeated temporal pairing and conditional reinforcement, subjects learn that A and B are predictive of one another: They are associated.

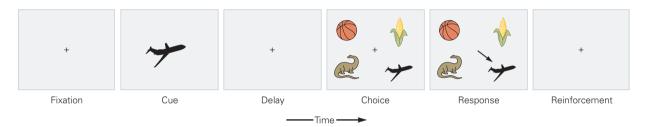

Figure 28–10A Delayed match-to-sample task. In this paradigm a trial begins with the appearance of a fixation spot that directs the subject's attention and gaze to the center of the computer screen. A sample image then appears briefly, typically for 500 ms, followed by a delay in which the display is blank. The delay can be varied to fit the experimental goals. Following the delay several test images, including the sample, are displayed. The monkey must choose the sample, typically either by pressing

a button or by a saccade to the stimulus. If the animal chooses the sample, it receives a small juice reward. In the task illustrated here all of the test images appear at once (a simultaneous match-to-sample task). They can also be presented sequentially (a sequential match-to-sample task). Although the trial's duration may be longer for the sequential task, this paradigm can be advantageous for electrophysiological studies by limiting the visual stimuli present at any time.

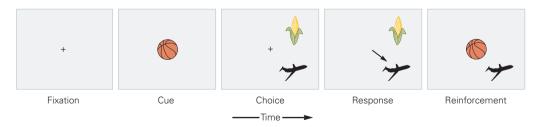

Figure 28–10B The paired-association task. This paradigm resembles the match-to-sample paradigm except that the sample and test stimuli are not the same. The subject must discover the correct association by trial-and-error learning. The task thus serves to build an association

between stimuli. The paired-association task can also incorporate a delay between presentation of the sample and test stimuli, and it can be used in both simultaneous (shown) and sequential forms.

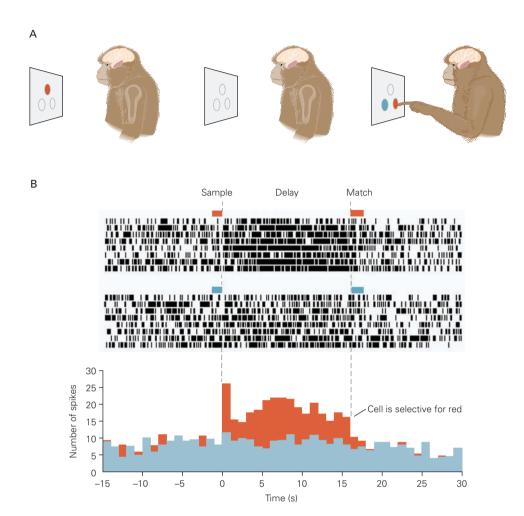

Figure 28–11 Neural activity representing an object is sustained while the object is held in working memory. (Reproduced, with permission, from Fuster and Jervey 1982.)

A. Monkeys were trained to perform a color match-to-sample task. For example, a red stimulus was first presented and the animal later had to choose a red stimulus from among many colored stimuli. The task incorporated a brief delay (1–2 seconds) between display of the sample and the match, during which information about the correct target color had to be maintained in working memory. The inferior temporal cortex is shown.

B. Peristimulus histograms and raster plots of action potentials illustrate responses of a single neuron in the inferior temporal cortex during the delayed match-to-sample task. The upper record is from trials in which the sample was red and the lower record from trials in which it was green. The recordings show that the cell responds preferentially to red stimuli. In trials with a green sample the activity of the neuron does not change, whereas in trials with a red sample the cell exhibited a brief burst of activity following presentation of the sample and continued firing throughout the delay. Many visual neurons in the inferior temporal and prefrontal cortices exhibit this kind of behavior.

This delay-period activity is thought to maintain information in short-term working memory. Delay-period activity in the inferior temporal and in prefrontal cortices differ in a number of ways. For one, the activity in the inferior temporal cortex is associated with the short-term storage of visual patterns and color information, whereas the activity in the prefrontal cortex encodes not only visual spatial information but also information about other sensory modalities. Delay-period activity in

the inferior temporal cortex also appears to be closely attuned to visual experience, for it encodes the sample image and can be eliminated by the appearance of another image (Figure 28–11).

In the prefrontal cortex, by contrast, delay-period activity is more likely to depend on task requirements and is not terminated by later sensory inputs, suggesting that it may play a role in the recall of long-term memories. Experiments by Earl Miller and colleagues

support this view. In these experiments monkeys were trained to associate multiple pairs of objects and then tested. Each behavioral test began with presentation of a single sample object. After a brief delay a monkey was shown a test object and asked to indicate whether it was the object paired with the sample during training.

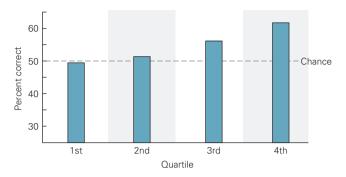

There are two possible ways to solve this task. During the delay the animal could remember the sample object by retaining a sensory code or thinking ahead to the expected object—the one associated with the sample during training—using a "prospective code." Remarkably, neuronal activity appears to transition from one to the other during the delay. Neurons in the prefrontal cortex initially encode the sensory properties of the sample object—the one just seen—but later begin to encode the expected (associated) object. As we shall see, such prospective coding in the prefrontal cortex may be the source of top-down signals to the inferior temporal cortex, activating neurons that represent the expected object and thus giving rise to conscious recall of that object.

The relation between long-term declarative memory storage and visual processing has been explored extensively in the context of remembered associations between visual stimuli. A century ago William James, a founder of the American school of experimental psychology, suggested that learning of visual associations might be mediated by enhanced connectivity between the neurons encoding individual stimuli. To test this hypothesis monkeys were trained to associate pairs of objects that had no prior physical or semantic relatedness. The monkeys were later tested while extracellular recordings of neurons in the inferior temporal cortex were made. Objects that had been paired often elicited similar neuronal responses, as one would expect if functional connections had been enhanced, whereas responses elicited by unpaired objects were unrelated.

To determine whether this pattern of selectivity was indeed temporally and conditionally tied to learning, Thomas Albright and colleagues recorded from individual inferior temporal neurons while monkeys were learning new visual associations. They found that responses to paired objects became more similar over the course of training (Figure 28–12). Most importantly, the changes in neuronal activity occurred on the same timescale as the behavioral changes and were dependent on successful learning.

The learning-dependent changes in the stimulus selectivity of inferior temporal cortex neurons are long-lasting, suggesting that this cortical region is part of the neural circuitry for visual associative memories. The results also support the view that learned associations are implemented rapidly by highly specific changes in

A Animals learn to associate pairs of stimuli

B After training neurons respond similarly to paired stimuli

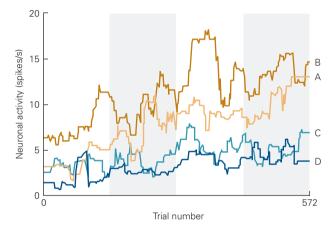

Figure 28–12 Object recognition is linked to associative memory. Monkeys learned associations between pairs of visual stimuli while activity was recorded from a neuron in the inferior temporal cortex. (Reproduced, with permission, from Messinger et al. 2001.)

A. Behavioral performance on a paired-association task is plotted for each quartile of a single training session (572 trials). The animal was presented with four novel stimuli and was required to learn two paired associations. As expected, performance began at chance (50% correct) and gradually climbed as the animal learned the associations.

B. Mean firing rates of an inferior temporal neuron recorded during the behavioral task described in part A. Each trace represents the firing rate during presentation of one of the four stimuli (A, B, C, or D). Although the responses to all stimuli were of similar magnitude at the outset, as the paired associations were learned the neuronal responses to the paired stimuli A and B began to cluster at a different level from responses to the paired stimuli C and D. The neuron's activity thus corresponded to the learned associations between the two pairs.

the strength of synaptic connections between neurons representing the associated stimuli.

We know that the hippocampus and neocortical areas of the medial temporal lobe—the perirhinal, entorhinal, and parahippocampal cortices—are

essential both for the acquisition of visual associative memories and for the functional plasticity of the inferior temporal cortex. The hippocampus and medial temporal lobe may facilitate the reorganization of local neuronal circuitry in the inferior temporal cortex as required to store visual associative memories. The reorganization itself may reflect a form of Hebbian plasticity, initiated by the temporal coincidence of the associated visual stimuli.

Associative Recall of Visual Memories Depends on Top-Down Activation of the Cortical Neurons That Process Visual Stimuli

One of the most intriguing features of high-level visual processing is the fact that the sensory experience of an image in one's visual field and the recall of the same image are subjectively similar. The former depends on the bottom-up flow of visual information and is what we traditionally regard as vision. The latter, by contrast,

is a product of top-down information flow. This distinction is anatomically accurate but obscures the fact that under normal conditions afferent and descending signals collaborate to yield visual experience.

The study of visual associative memory has provided valuable insights into the cellular mechanisms underlying visual recall. As we have seen, visual associative memories are stored in the visual cortex through changes in the functional connectivity between neurons that independently represent the associated stimuli. The practical consequence of this change is that a neuron that responded only to stimulus *A* prior to learning will respond to both stimulus *A* and stimulus *B* after these stimuli have been associated (Figure 28–13). Activation of an *A*-responsive neuron by the associated stimulus *B* can be viewed as the neuronal correlate of top-down recall of stimulus *A*.

Neurons in the inferior temporal cortex exhibit precisely this behavior. The activity correlated with cued recall is nearly identical to the bottom-up activation by the stimulus. These neurophysiological findings

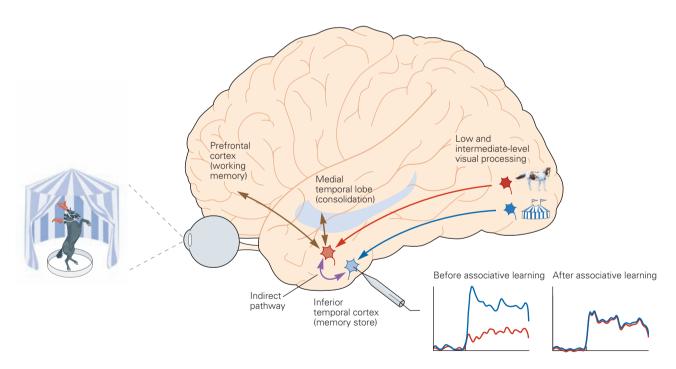

Figure 28–13 Circuits for visual association and recall. Bottom-up signals—afferent signals initiated by objects in the observer's visual field—lead to representation of those objects in the inferior temporal cortex. Before associative learning, a neuron (light blue) responds well to the circus tent but not to the horse. Learned associations between objects are consolidated in the inferior temporal cortex by strengthening connections between neurons representing each of the paired objects

(the indirect pathway in the figure). That consolidation is mediated by memory structures of the medial temporal lobe. Thus recall of the circus tent following presentation of the horse is achieved by activating the indirect pathway. Indirect activation can also be triggered by the contents of working memory (feedback from the prefrontal cortex). Under normal conditions visual experience is the product of a combination of direct and indirect inputs to the inferior temporal cortex.

are supported by a number of brain-imaging studies that have identified selective activity in the visual cortex during cued and spontaneous recall of objects.

Although learned associations between images are likely to be stored through circuit changes in the inferior temporal cortex, the prefrontal cortex is essential for activating these circuits for conscious recall. The afferent signal for one of a pair of images might be received by the inferior temporal cortex and relayed to the prefrontal cortex, whereupon the information would be maintained in working memory. As we have seen, the signaling of many prefrontal neurons during the delay period of a delayed match-to-sample task initially encodes the sample image but changes to encode the associated image that is expected to follow. Signals from prefrontal cortex to the inferior temporal cortex would selectively activate neurons representing the associated image, and that activation would constitute visual recall.

An Overall View

The eminent neuropsychologist Hans-Lukas Teuber once wrote that failure of object recognition "would appear in its purest form as a normal percept that has somehow been stripped of its meaning." Indeed, the assignment of meaning is one of the most important processes in vision and forms the core of the high-level stage of visual processing.

Although meaning is itself difficult to define, it has generally acknowledged connotations. For example, meaning suggests the ability to identify things that are the same. One of the most striking features of object recognition is the ability to identify an object as the same despite an infinite variety of retinal images. This occurs because a neuron in the inferior temporal cortex is activated by the various retinal images of the same object. Similarly, visual neurons in the prefrontal cortex fire in response to objects that are physically different but semantically related.

Meaning may also connote function, utility, or intention. In the case of visual recognition meaning is formed by the observer's prior sensory experiences and the acquired associations between these experiences. These attributes are fundamental in high-level visual processing and include enhanced perceptual and neuronal selectivity for objects that are commonplace as well as associative links between neuronal representations of objects.

Although much is now known about the neuronal *correlates* of object recognition, very little is yet known

about the circuits that *cause* these neuronal representations. Even less is known about the cellular and molecular mechanisms by which these circuits are modified by visual experience. Thus future experiments need to address a number of important questions.

How are categorical representations formed? What is the mechanism by which incoming sensory stimuli are compared with stored representations to achieve object recognition? If we accept that associative memories are stored as patterns of connections between neocortical neurons, what then are the specific contributions of the hippocampus and neocortical structures of the medial temporal lobe, and by what cellular mechanisms do they exert their influences? And how does reinforcement cement changes in the strength of the interconnections between neurons that are presumed to underlie associative memories?

The confluence of molecular-genetic, cellular, neurophysiological, and behavioral approaches in solving these and other problems promises a bright future for understanding of high-level visual processing.

An Overall View

TISION REQUIRES EYE MOVEMENTS. Small eye movements are essential for maintaining the contrast of objects that we are examining. Without these movements the perception of an object rapidly fades to a field of gray, a phenomenon correlated with the decreased response of neurons in area V1 (see Chapter 25). Large eye movements direct the fovea from one object to another. These movements or saccades bring the high resolution of the fovea to bear on different regions of the visual field, exploiting the high density of photoreceptors in the central fovea. Without saccades this high-resolution processing could be achieved only by moving the head or body.

The preceding chapters have described how visual images are constructed, beginning with the processing of intensity and contrast, then the integration of visual primitives, and finally the high-level processing that leads to the recognition of objects. But the visual system involves more than just object recognition. It must

also support the brain's goal of assigning significance to objects in order to develop strategies for interacting with the environment. Thus the brain must be able to select some objects for greater examination while ignoring others.

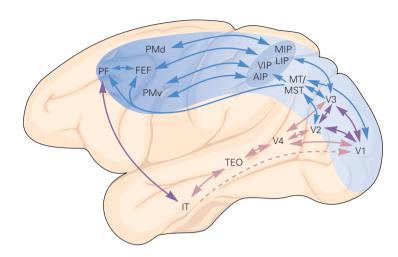

In this chapter we consider how saccades support that goal. We first consider the essential benefits that saccades provide, shifting attention in the visual field and assisting with the preparation to grasp objects. We then consider the brain mechanisms that solve a major problem created by saccades—the fact that the retinal image is abruptly displaced with every saccade.

In shifting our attention from how the brain constructs a visual scene to how it uses visual information to plan actions, we now concentrate on the region of the brain referred to as the dorsal visual pathway (Figure 29–1). This pathway extends from V1 to the regions in parietal cortex that continue the intermediate level of visual processing, such as the middle temporal area, and then to other regions of parietal and frontal cortex. The regions particularly relevant to this chapter are in the parietal cortex, such as the lateral intraparietal area, but include also the frontal eye field region of the frontal cortex.

Successive Fixations Focus Our Attention in the Visual Field

A saccade usually lasts less than 40 ms and redirects the center of sight in the visual field. Saccades occur several times per second, and each intervening period

Figure 29–1 Pathways involved in visual processing for action. The dorsal visual pathway (blue) extends to the posterior parietal cortex and then to the frontal cortex. The ventral visual pathway (pink) is considered in Chapter 27. (AIP, anterior intraparietal cortex; FEF, frontal eye field; IT, inferior temporal cortex; LIP, lateral intraparietal cortex; MIP, medial intraparietal cortex; MST, medial superior temporal cortex; MT, middle temporal cortex; PF, prefrontal cortex; PMd, PMv, dorsal and ventral premotor cortices; TEO, occipitotemporal cortex; VIP, ventral intraparietal cortex; V1–V4, areas of visual cortex.)

of fixation lasts several hundred milliseconds. The Russian psychologist Alfred Yarbus was the first to show that the pattern of saccades made by a human looking at a picture reflected the cognitive purpose of vision. He found that saccades were not directed equally to all parts of a scene. Areas of apparent interest were fixated most frequently, whereas background objects were ignored. For example, the faces of people were fixated repeatedly (Figure 29–2).

The image on the fovea shifts with each saccade, yet we perceive a stable visual world. How does that come about? One possibility is that the brain creates a representation of the entire visual scene from a series of visual fixations across the scene and that what we see is this summed representation of the visual world. If that were so, we should have detailed knowledge of the entire visual scene at any given instant.

A series of experiments on change blindness showed that this is not the case. These experiments involved changing a picture during the brief time when the viewer made a saccade from one part of the scene to another. If there were a relatively complete internal representation of the scene before the saccade, then any substantial change made during the saccade should have been recognized. But even a large change frequently went unrecognized. This change blindness occurred even when there were no actual eye movements, as when two pictures were shown in succession with only a brief blank between them to simulate the effect of an eye movement (Figure 29–3).

The results of the change-blindness experiments are inconsistent with the hypothesis that we are continually updating a complete representation of the visual field from second to second. Instead we seem to pay attention

to only certain fragments of the scene. This selective visual attention relies on the saccades that bring the images of desired parts of the visual field onto the fovea.

Attention Selects Objects for Further Visual Examination

In the 19th century William James described attention as "the taking possession by the mind in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought. It implies withdrawal from some things in order to deal effectively with others." James went on to describe two kinds of attention: "It is either passive, reflex, nonvoluntary, effortless or active and voluntary. In passive immediate sensorial attention the stimulus is a sense-impression, either very intense, voluminous, or sudden ... big things, bright things, moving things ... blood."

More recently these two kinds of attention have been termed *involuntary* (exogenous) and *voluntary* (endogenous) attention, or bottom-up and top-down attention. Your attention to this page as you read it is an example of voluntary attention. If a bright light suddenly flashed, your attention would probably be pulled away involuntarily from the page.

Voluntary attention is closely linked to saccades because the fovea has a much denser array of cones than the peripheral retina (see Figure 26–1), and this permits a finer-grain analysis of objects than is possible with peripheral vision.

Attention, both voluntary and involuntary, has several measurable effects on human visual performance: It shortens reaction time and makes perception

Figure 29-2 Eye movements during vision. A subject viewed this painting (An Unexpected Visitor by Ilya Repin) for several minutes, making saccades to selected fixation points—primarily faces—that presumably were of most interest. Lines indicate saccades, and spots indicate points at which the eyes fixated. (Reproduced, with permission, from Yarbus 1967.)

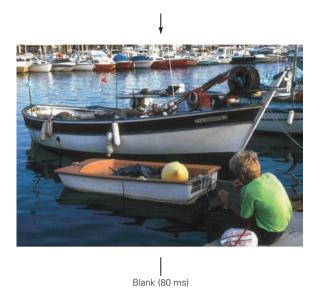

more sensitive. This increased sensitivity includes the abilities to detect objects at a lower contrast and ignore distracters close to an object. The abrupt appearance of a behaviorally irrelevant cue such as a light flash reduces the reaction time to a test stimulus presented 300 ms later in the same place, but increases reaction time when the test stimulus appears at a different place. The light flash involuntarily draws attention to itself, and attention to that location is maintained for a brief period, thus accelerating the visual response to the later test stimulus at the location. Similarly, if a subject plans a saccade to a particular part of the visual field, the contrast threshold at which any object there can be seen is lowered by 50%. The saccade, under voluntary control, draws attention to its goal.

Activity in the Parietal Lobe Correlates with **Attention Paid to Objects**

Clinical studies have long implicated the parietal lobe in the process of visual attention. Patients with lesions of the right parietal lobe have normal visual fields when their visual perception is studied with a single stimulus in an uncomplicated visual world. However, when presented with a more complicated world, with objects in the right (ipsilateral) and left (contralateral) visual hemifields, they tend to report more of what lies in the right visual hemifield.

This deficit, known as neglect syndrome (see Chapter 17), arises because attention is focused on the visual hemifield ipsilateral to the lesion. Even when

Blank (80 ms)

Blank (80 ms)

patients are presented with only two stimuli, one in each field, they report seeing only the stimulus in the ipsilateral hemifield. They do not have the ability to focus attention in the hemifield contralateral to the lesion, and as a result they may not see everything in that hemifield, even though the sensory pathway from the eye to the striate and prestriate cortex is intact.

This neglect of the contralateral visual hemifield extends to the neglect of the contralateral half of individual objects. Patients with right parietal deficits often have difficulty reproducing drawings. When asked to draw a clock, for example, they may force all of the numbers into the right side of the face (see Figure 17–11), or when asked to draw a candlestick they may draw only its right side (Figure 29–4).

The process of attentional selection is evident at the level of single parietal neurons in the monkey. The responses of neurons in the lateral intraparietal area to a visual stimulus depend not only on the physical properties of the stimulus but also on how the monkey behaves toward it. When a monkey fixates a spot, a stimulus in the neuron's receptive field evokes a moderate response. When the animal must attend to the same stimulus, the stimulus evokes a greater response, often by a factor of two. Conditions that evoke both involuntary and voluntary attention—the abrupt onset of a visual stimulus in the receptive field or the planning of a saccade to the receptive field of the neuron—evoke still greater responses (Box 29–1).

Neurons in the lateral intraparietal area collectively represent the entire visual hemifield, but the neurons active at any one moment represent only the important or salient objects in the hemifield. That is, a few salient objects—such as the goal of an eye movement or a recent flash—evoke responses in a subset of neurons, and the activity of these neurons is greater than the background activity of the entire population of cells. Both the attention mechanisms and saccades are directed to the peak of the map.

The absolute value of the response evoked by a salient stimulus does not determine whether the stimulus is the most likely saccade target or most highly attended stimulus. When a monkey plans a saccade to

Figure 29–3 Change blindness. In this example one picture is presented followed by a blank for 80 ms, followed by the second picture, another blank, and a repeat of the cycle. The subject is asked to report what changed in the scene. There is a substantial and, once perceived, obvious change between the two pictures. It takes multiple repetitions for most observers to detect the difference. (Reproduced, with permission, from Ronald Rensink.)

Figure 29–4 Drawing of a candlestick by a patient with a right parietal lesion. The patient neglects the left side of the candlestick, drawing only its right half. (Reproduced, with permission, from Peter Halligan.)

a stimulus in the visual field, attention is on the goal of the saccade, and the activity evoked by the saccade plan lies at the peak of the salience map. However, if a bright light appears elsewhere in the visual field, attention is involuntarily drawn to the bright light, which evokes more neuronal activity than does the saccade plan. Thus the locus of attention can be ascertained only by examining the entire salience map and choosing its peak; it cannot be identified by monitoring activity at one point alone.

The Visual Scene Remains Stable Despite Continual Shifts in the Retinal Image

Saccades create a major challenge for visual processing. Successive saccades produce a series of discrete images, each centered where the eye is looking (Figure 29–8). Although this result might be expected to resemble a home movie with the camera moving about in a

jumpy fashion, it does not. How visual scenes remain stable despite repeated shifts in focus has been a source of speculation since the 1600s.

Although the basis of this stability is not understood, changes in perception at the time of a saccade offer clues. At the time of a saccade, objects in the perceived scene do not have exactly the same spatial arrangement as in the visual field. The perceived scene appears spatially compressed such that stimuli presented just before the saccade appear closer to the presaccade point of fixation, whereas stimuli presented after the saccade appear to be closer to the saccade's target (Figure 29–9).

This spatial compression is usually no larger than half the size of the saccade and occurs only when there is a larger visual scene. It is not due to stimuli falling on different parts of the retina because of the saccade, for stimuli presented before the saccade also appear compressed. These considerations indicate that some extravisual information is involved in the processing of saccade commands.

What neuronal mechanism might underlie this apparent shift in images at the time of saccades? Neurons in the parietal cortex alter their activity preceding saccades in ways that seem remarkably related to the perceptual phenomenon. When a monkey is about to make a saccade, a neuron becomes less sensitive to the stimulus already present in its receptive field and begins to respond to the stimulus that will be within the receptive field after the saccade (Figure 29–10).

This shift in selectivity can begin even before the saccade commences. Not every stimulus in the visual field will activate the neuron, only those that will fall in the neuron's receptive field after the saccade. After completion of the saccade, the neuron is again activated only by those stimuli that are actually within its receptive field.

These observations reveal two neuronal mechanisms that contribute to the stabilization of the visual scene during saccades. First, neurons shift their receptive fields from one part of the visual field to another before the saccade occurs. This shift in receptive field is comparable to the change in perceived location of stimuli before the saccade and might contribute to the compression in the perceived visual scene at the time of the saccade. The output of the parietal neurons is interpreted as indicating that stimuli are present in one part of the visual field, although at the time of the saccade the neurons are responding to stimuli that will be in their receptive field after the saccade as well as to stimuli presently within the receptive field. If the brain assumes that stimuli at both locations are joined

together, this could account for the compression of the perceived scene.

Second, because the new receptive-field position after a saccade depends on the amplitude and direction of the saccade, the parietal neurons must have advance information about the saccade. There are only two potential sources of this information. One is the feedback to the brain from the peripheral proprioceptors in the eye muscles that could inform the brain that the eye is moving. This is unlikely because both the receptive field shifts and the perceptual compression begin even before the eye moves, and the cortical representation of eye position lags the eye movement by nearly 100 ms. The second potential source is the motor system that controls movement of the eyes (see Chapter 39). This system could send a copy of its signals, known as a corollary discharge or efference copy, to the parietal cortex to inform it that the saccade is about to occur. This signal would provide the information on the amplitude and direction of the impending saccade needed to compute the new receptive-field location before the saccade actually occurs.

The specific source of a corollary discharge to the parietal cortex remains unknown, but neurons in the frontal eye field that show shifts in receptive-field sensitivity similar to those in the lateral intraparietal area do receive an identified corollary discharge. The source of this corollary discharge is the saccade-generating neurons in the superior colliculus. Because the parietal cortex and frontal eye field have strong reciprocal connections, the same corollary discharge input could affect both structures.

The corollary discharge from the superior colliculus reaches the frontal eye field through a relay in a higher-order thalamic nucleus, the medial dorsal nucleus (Figure 29–11A). Neurons in this nucleus signal the amplitude and direction of an impending saccade and could therefore provide the information needed to shift the receptive fields of neurons in the frontal eye field and lateral intraparietal area before the saccade occurs. But do they? Inactivation of neurons in the thalamic relay greatly reduces the ability of frontal eye field neurons to shift their receptive fields prior to a saccade (Figure 29–11B), providing evidence that the shift does depend on an efferent copy of the saccade motor program.

Vision Lapses During Saccades

During a saccade the visual scene is not only displaced but also swept rapidly across the retina as the eye moves at high speed. Because we are unaware of this sweep, the American psychologist Edwin Holt at the beginning of the 20th century posited that there must be a central anesthesia during the eye movement.

But this cannot be true, for there are instances in which vision is quite clear during a saccade. An object can be seen during a saccade if it is moving as fast as the eye and in the same direction, as occurs for example during a saccade in the direction of a car passing the observer in a train. What may instead be the case is that much of the visual scene is ordinarily blurred by the speed of eye movement. But why does the blur not reach consciousness? Two underlying mechanisms in combination probably account for this perceptual omission.

The first mechanism is visual masking, which is the effect one image has on another when the two are presented in rapid succession. For example, a higher-contrast image reduces or eliminates the perception of a lower-contrast image. This happens during a saccade: The rapid movement of the eye over the scene produces a blurred, low-contrast image that is masked by the stable, high-contrast images before and after the saccade. This masking can be demonstrated by an experiment in which high-contrast images are not present before or after the saccade. Under these conditions a blurred image is seen. If a high-contrast image is present after the saccade, however, the blur vanishes (Figure 29–12A).

There are conditions, however, when extravisual input, such as a corollary discharge, also must be present. For example, a coarse grating can be seen even when it moves across the retina at the high speeds of saccades if the bars are oriented in the same direction as the saccade (Figure 29–12B). When the eyes are fixated, low- and middle-frequency gratings can be seen but very high-frequency gratings are not well seen. In contrast, during a saccade the detection of low-frequency gratings is markedly impaired but the highest-frequency gratings remain visible. Thus the reduction of sensitivity during the saccade, known as saccadic suppression, is specific for low-frequency gratings.

These low spatial frequencies are precisely those most likely to escape the effects of visual masking, so that a reduction in sensitivity to these stimuli must result from extravisual input such as a corollary discharge. They are also the best stimuli for the magnocellular component of the geniculostriate pathway, for the parvocellular pathway is more sensitive to high spatial frequencies. Both masking and corollary discharge must jointly act to produce the saccadic suppression that usually eliminates the intrusive motion of the scene during saccades.

Box 29–1 The Effect of Behavioral Significance on Neuronal Responses

The responses of neurons in the lateral intraparietal area to visual stimuli vary with the behavioral significance of stimuli as well as the physical characteristics of the stimuli. This can be demonstrated by recording from neurons while a monkey makes eye movements across a stable array.

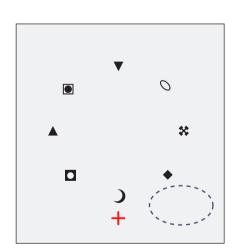

Stable objects in the visual world are rarely the objects of attention. In the lateral intraparietal area, as in most other visual centers of the brain, neuronal receptive fields are retinoptic, that is, they are defined relative to the center of gaze. As a monkey scans the visual field, fixed objects enter and leave the receptive fields of neurons with every eye movement without attracting the animal's attention (Figure 29–5).

The abrupt appearance of a visual stimulus can evoke involuntary attention, however. When a light flashes in the receptive field of a lateral intraparietal neuron, that cell responds briskly (Figure 29–6A). In contrast, a stable, task-irrelevant stimulus evokes little response when eye movements bring it into the neuron's receptive field (Figure 29–6B).

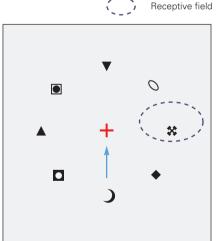

When the stimulus appears abruptly outside the receptive field, a saccade brings the attention-commanding stimulus into the receptive field, evoking a large response from the neuron (Figure 29–6C). When the monkey makes the saccade, the objects in the visual field are identical in both cases. However, the stable stimulus is presumably unattended, whereas the light flash evokes attention and provokes a much larger response. Stable objects can evoke enhanced responses when they become relevant to the animal's current behavior.

In the experiment of Figure 29–7 the monkey begins by fixating one of several images outside the receptive field. A cue appears, also outside the receptive field, that tells the monkey which image it should fixate after a saccade to the center of the array of images. If this second target is already in the receptive field the stimulus evokes a large response. If it is not, the stimulus evokes little response when the saccade brings it into the receptive field. Thus attention modulates the activity of neurons in the lateral intraparietal cortex (LIP) regardless of how that attention is evoked.

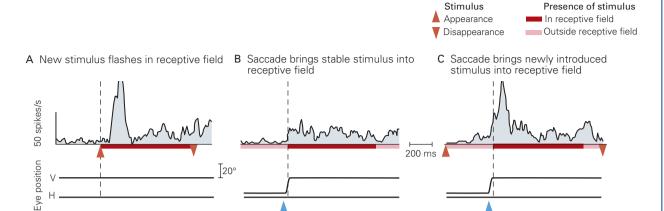

Fixation point Saccade

Saccade

Figures 29–6 A neuron in the lateral intraparietal area fires only in response to salient stimuli. In each panel neuronal activity along with horizontal (H) and vertical (V) eye positions are plotted against time.

A. A stimulus flashes in the receptive field while the monkey fixates.

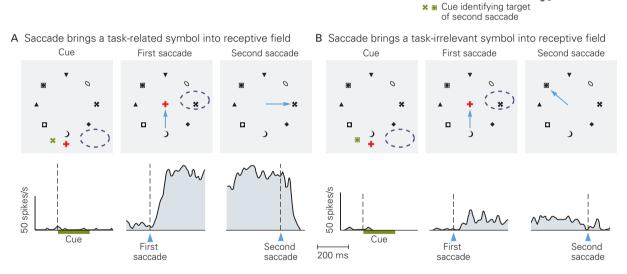

B. The monkey makes a saccade that brings a stable, taskirrelevant stimulus into the receptive field.

Saccade

C. The monkey makes a saccade that brings the position of the recent light flash into the receptive field.

+ Fixation Point

Receptive field

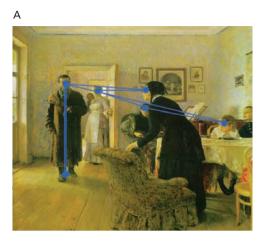

Figures 29–7 A neuron in the lateral intraparietal area fires before a saccade to a stable object. On each trial one object in a stable array becomes significant to the monkey because the monkey must make a saccade to it. The monkey fixates a point outside the array, and a cue that matches an object in the array appears outside the neuron's receptive field. The monkey must then make a saccade to the center of the array and a second saccade to the object that matches the cue. Two experiments are shown, each in three panels. The left panel shows the response to the cue when it appears outside the receptive field, the center panel shows the response after the first saccade that brings the cued object into the receptive

field, and the right panel shows the response just before the saccade to the cued object. The cues are shown here in green for clarity but were black in the experiment.

A. The monkey is trained to make the second saccade to the cued object; the cell fires intensely when the first saccade brings the object into the receptive field.

B. The monkey is trained to make the second saccade to an object outside the receptive field; the cell fires much less when the saccade brings the task-irrelevant stimulus into the receptive field. The visual scene at the time of the saccade is identical in both experiments.

R

Figure 29–8 Saccades present the brain with rapid changes in the retinal image. (Reproduced, with permission, from Wurtz 2008.)

- A. Saccades (blue lines) result in a series of fixations at various locations in the visual field (blue dots)
- **B.** The successive fixations are represented here as isolated foveal images.
- **C.** The sensory signals for successive fixations provide no information about the location of each fixation. The visual information from each fixation is interspersed with the blurs from the intervening saccades.

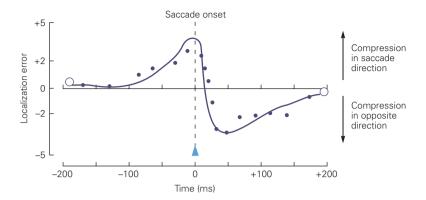

Changes in neuronal activity that are associated with a reduction of visual sensitivity have been found along the visual pathway and are probably due to both visual masking and corollary discharge. Neuronal correlates of visual masking are evident in the responses of neurons in the primary visual cortex. Many V1 neurons fire when eye movement sweeps a lone stimulus across their receptive fields but do not fire when another stimulus falls within their receptive fields just before the saccade (Figure 29–13A). The masking effect of the stimulus falling within the receptive fields before the saccade is analogous to the stationary visual scene before and after a saccade masking the blur of the scene during the saccade. The same masking occurs when moving stimuli sweep across the receptive fields at saccade speeds while the monkey continues to fixate. This neuronal masking effect therefore stems entirely from visual processing; no saccade is required.

Saccadic suppression due to corollary discharge is most pronounced for stimuli with low spatial frequency and high contrast, the stimuli that are most effective for activating neurons in the magnocellular pathway of the visual system. During saccades the activity of neurons in the lateral geniculate nucleus is altered and frequently reduced, but the suppression is limited and not confined to the magnocellular layers. In the absence of visual masking, neurons in cortical area V1 show little suppression during saccades so the effect of corollary discharge on the geniculocortical pathway is limited. But in the regions of extrastriate cortex devoted to motion processing, the middle temporal and medial superior temporal areas, there is clear suppression of visual stimuli during saccades that could result from a corollary discharge.

When eye movement sweeps the stimulus across the retina, neurons do not respond, but when the stimulus is moved at the same speed in front of the stationary eye, these same neurons fire robustly (Figure 29–13B). The likely explanation of this difference is that a corollary discharge of the saccade command reduces the response of the neurons to the stimulus. One possible source of this corollary discharge is the superior-collicular signal that shifts receptive fields in frontal and parietal cortex. This is a likely possibility because visual neurons in the superior colliculus are also suppressed during saccades and this suppression stems from corollary discharge.

At both the neuronal and behavioral levels, then, there is evidence that visual masking and corollary discharge act together to reduce the disruption of vision during saccades.

Figure 29–9 Compression of visual space at the time of a saccade. The perceived location of a stimulus presented just before or after a saccade is shifted toward the target of the saccade. (Reproduced, with permission, from Honda 1991.)

The Parietal Cortex Provides Visual Information to the Motor System

Vision interacts with the supplementary and premotor systems to prepare the hands for action. When you pick up a pencil your fingers are separated from your thumb by the width of a pencil; when you pick up a drink your fingers are separated from your thumb by the width of the glass. The visual system helps to adjust the grip width before your hand arrives at the

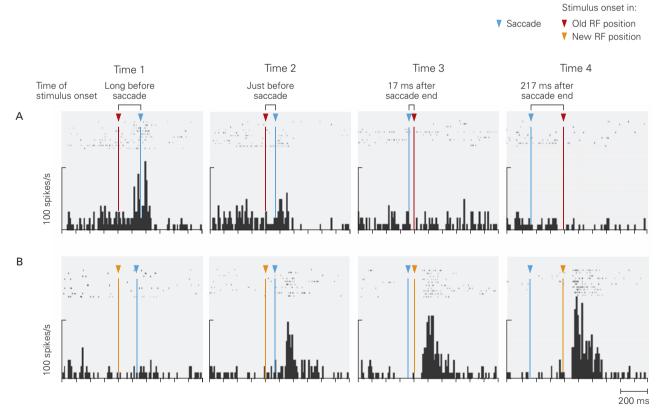

Figure 29–10 Activity in a parietal cortex neuron anticipates a change in position of its receptive field due to a saccade. Neuronal activity is aligned to the stimulus onset. The response of the cell to a stimulus in its receptive field decreases, even

before the onset of the saccade (A), while its response to a stimulus in the anticipated postsaccade position of its receptive field increases (B). (Modified, with permission, from Nakamura and Colby 2002.)

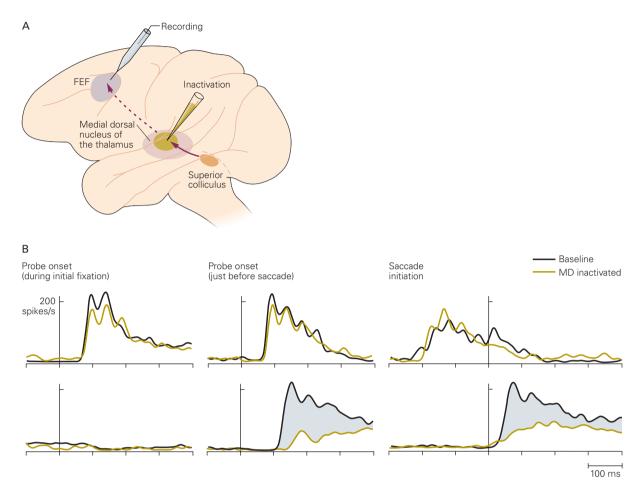

Figure 29–11 A corollary discharge from the motor program for saccades directs presaccade shifts in receptive-field location for frontal eye field neurons.

A. One possible pathway for a corollary discharge to the cerebral cortex originates in saccade-generating neurons in the superior colliculus, passes through the medial dorsal nucleus of the thalamus, and terminates in the frontal eye field (FEF) in the frontal cortex.

B. When the medial dorsal nucleus (MD) is inactivated, the response to a stimulus currently in the receptive field is unaffected (upper records), whereas the response to a stimulus in the prospective (postsaccade) location of the receptive field is severely impaired (lower records). This result demonstrates that a corollary discharge from the saccade motor program directs the shift in the neuron's receptive field properties. (Modified, with permission, from Sommer and Wurtz 2008.)

object. Similarly, when you insert a letter into a mail slot your hand is aligned to place the letter in the slot. If the slot is tilted, your hand tilts to match.

Patients with lesions of the parietal cortex cannot adjust their grip width or wrist angle using visual information alone, even though they can verbally describe the size of the object or the orientation of the slot. Conversely, patients with intact parietal lobes and deficits in the ventral stream cannot describe the size of an object or its orientation but can adjust their grip width and orient their hands as well as normal subjects can. The parietal lobe is a critical source of

information about the visual properties of the targets of movement.

As described in Chapter 16, the representation of space in the parietal cortex is not organized into a single map like the retinotopic map in primary visual cortex. Instead it is divided into four areas that analyze the visual world in ways appropriate for individual motor systems and project to areas of premotor cortex that control individual movements (Figure 29–14).

The neural operations behind visually guided movements involve identifying targets, specifying their qualities, and ultimately generating a motor program

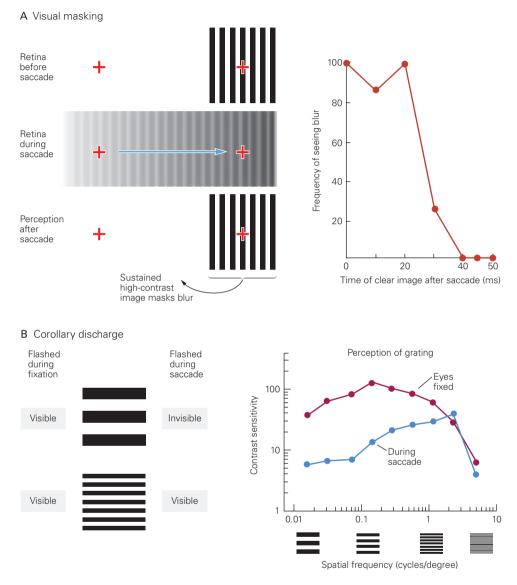

Figure 29-12 Saccadic suppression.

A. Visual masking. When a subject makes a saccade to a stable, high-contrast image (top), there is blurred image on the retina (middle) but the viewer sees only the high-contrast image after the saccade (bottom) and never a blur. If the high-contrast image is present only during the saccade or slightly after, the viewer sees a blur (zero on the horizontal axis of the graph). When the high-contrast image remains on the screen for a longer time after the saccade, the blurred image is no longer evident (40 ms on the graph): The high-contrast image

after the saccade masks the low-contrast blur. (Reproduced, with permission, from Campbell and Wurtz 1978.)

B. Corollary discharge. A subject can see a coarse grating (low spatial frequency) much better when it is presented briefly during fixation than when it is presented during a saccade. A fine grating (high spatial frequency) is seen just as well during a saccade as during fixation (nearly superimposed red and blue data points at 2 cycles per degree). (Reproduced, with permission, from Burr, Morrone, and Ross 1994.)

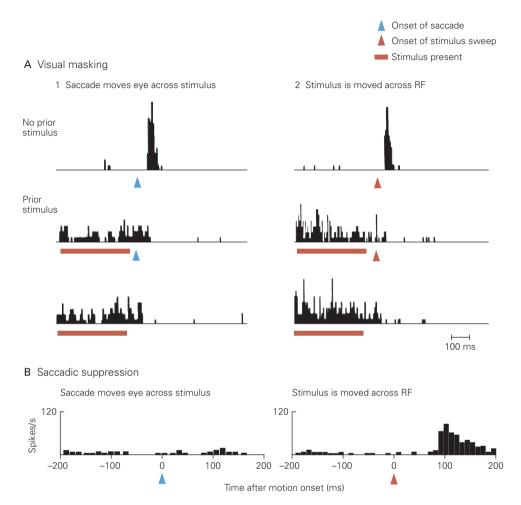

Figure 29–13 Neuronal correlates of saccadic suppression.

A. Visual masking. 1. When a monkey makes a saccade across a stimulus on a blank screen, a neuron in V1 responds (upper record). However, if another stimulus falls in the neuron's receptive field before the saccade, the neuron does not respond to the stimulus flashed during the saccade (middle record), and the neuronal response resembles the response to the first stimulus alone (lower record). 2. The same neuron responds if the stimulus is swept across its receptive field (RF) while the eye is stationary (upper record) but does not respond to the same stimulus motion when it is preceded by a stationary stimulus within the receptive field (middle record).

Again the neuron's response resembles the response to the first stimulus alone. This lack of response is a correlate of the masking effect of one visual stimulus on another. (Modified, with permission, from Judge, Wurtz, and Richmond 1980.)

B. Saccadic suppression. A middle temporal area neuron does not fire during a saccade across a stationary stimulus (left) but does fire when the stimulus is moved at the same speed in front of the stationary eye (right). The difference is taken as evidence that a corollary discharge from the saccade motor system suppresses excitation of the neuron during the saccade. (Modified, with permission, from Thiele et al. 2002.)

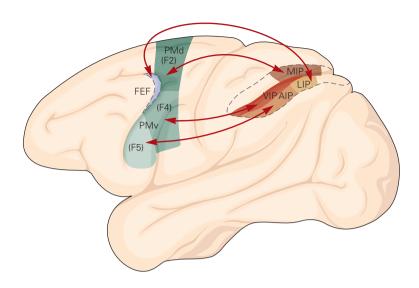

to accomplish the movement. Neurons in the parietal cortex provide the visual information necessary for independent movements.

The anterior intraparietal cortex has neurons that signal the size, depth, and orientation of objects that can be grasped. Neurons in this area respond to stimuli that could be the targets for a grasping movement, and also respond when the animal makes the movement

(Figure 29–15). Similarly, neurons in the medial intraparietal cortex represent the targets for reaching movements and project to the frontal area that generates the premotor signal for these movements.

The ventral intraparietal area has bimodal neurons that respond to both tactile and visual stimuli in the face (Figure 29–16). This area projects to the face area of premotor cortex. Finally, neurons in the lateral

Figure 29–14 Four functionally discrete areas in the intraparietal sulcus project to areas in the premotor cortex. The medial intraparietal cortex (MIP) represents targets of arm movements and projects to the arm-control area of F2 in the dorsal premotor area (PMd). The lateral intraparietal cortex (LIP) represents targets of eye movements and projects to the frontal eye field (FEF). The anterior intraparietal cortex (AIP) represents targets for grasping and projects to the hand-control area of F5 in the ventral premotor area (PMv). The ventral intraparietal cortex (VIP) represents the face and projects to the face-control area of F4 in the ventral premotor area. (Reproduced, with permission, from Rizzolatti, Lupino, and Matelli 1998).

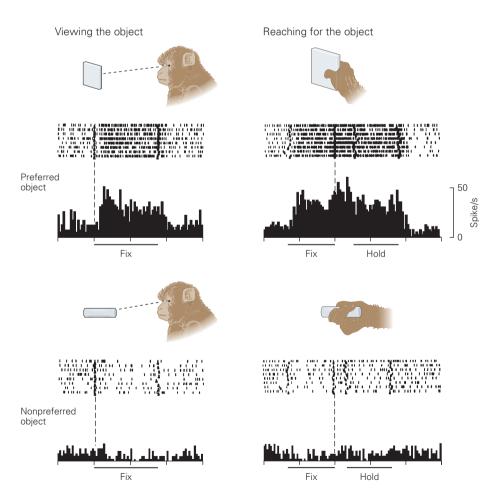

Figure 29–15 Neurons in the anterior intraparietal cortex respond selectively to specific shapes. The neuron shown here is selective for a rectangle, whether viewing the object or

reaching for it. The neuron is not responsive to the cylinder in either case. (Reproduced, with permission, from Murata et al. 2000.)

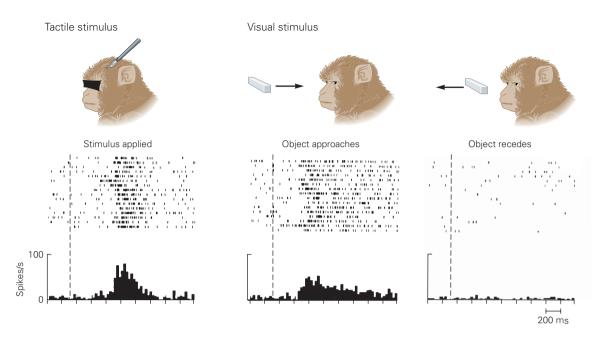

Figure 29–16 Bimodal neurons in the ventral intraparietal cortex of a monkey respond to both visual and tactile stimuli. The neuron shown here responds to tactile stimulation

of the monkey's head or to a visual stimulus coming toward the head, but not to the same stimulus moving away from the head. (Reproduced, with permission, from Duhamel et al. 1997.)

intraparietal area describe the targets for saccadic eye movements and project to the frontal eye field.

An Overall View

The visual cortex is interconnected by ventral and dorsal streams of neuronal processing. The ventral stream provides information about the nature of the objects represented; the dorsal stream provides information that the oculomotor and skeletal motor system can use for movement.

A critical function of the dorsal stream is to mediate attention, which is necessary in order to select objects in the visual field for further analysis. Neurons in the parietal lobe of the monkey respond more vigorously to attended objects than to unattended ones, and the activity of neurons in the monkey's parietal lobe mirrors the attention paid to certain objects in the environment.

Because visual information enters the brain through eyes that are constantly moving, the brain requires a mechanism to compensate for eye movements, constructing a stable visual world from successive fixations. Information supplied by the motor system through corollary discharges is used to adjust the receptive fields of visual neurons to compensate for intervening eye movements. The parietal lobe has a number of distinct representations of the visual field, each of which provides information to a specific motor subsystem.

to distinguish a remarkable range of sounds—from the intimacy of a whisper to the warmth of a conversation, from the complexity of a symphony to the roar of a stadium. Hearing begins when the cochlea, the snail-shaped receptor organ of the inner ear, transduces sound energy into electrical signals and forwards them to the brain. Our ability to recognize small differences in sounds stems from the cochlea's capacity to distinguish among frequency components and to inform us of both the tones present and their amplitudes.

Deafness can be devastating. For the elderly, hearing loss can result in a painful and protracted estrangement from family, friends, and colleagues. Children may lack hearing as a result of pre- or perinatal infections and especially of genetic conditions, which affect one child in a thousand. Such children are often deprived of the normal avenue to the development of speech, and thus of reading and writing as well. It is for this reason that a modern pediatric examination must include an assessment of hearing. Many children thought to be cognitively impaired are found instead to be hard of hearing, and their intellectual development resumes its normal course when this problem is corrected.

Acute hearing loss in the intermediate years exacts an enormous price for two reasons. First, hearing plays an important, but often overlooked, role in our psychological well-being. Daily conversation with family and colleagues helps to establish our social context. The abrupt loss of such social intercourse as a result of sudden deafness leaves a person distressingly lonely and may lead to depression and even suicide. Hearing also serves us in another, more subtle way. Our auditory system is a remarkably efficient early warning system,

subconsciously informing us about our environment. For example, when other people enter the room or approach us we often hear them before we see them. More obviously, awareness of fire alarms and the sirens of emergency vehicles can be lifesaving. Deafness may leave a person with an ominous sense of vulnerability to unheard changes in the environment.

Hearing loss is often accompanied by another distressing symptom, tinnitus, or ringing in the ears. By interfering with concentration and disrupting sleep, tinnitus can exasperate, depress, and even madden its victims. Because on rare occasions tinnitus stems from lesions to the auditory pathways, such as acoustic neuromas, it is important in neurological diagnosis to exclude such causes. Most tinnitus, however, is idiopathic: Its cause is uncertain. Some drugs trigger the condition; antimalarial drugs related to quinine and aspirin at the high dosages used in the treatment of rheumatoid arthritis are notorious for this. Often, however, tinnitus occurs at high frequencies to which a damaged ear is no longer sensitive. In these instances tinnitus may reflect hypersensitivity in the deafferented central nervous system, a phenomenon analogous to phantom-limb pain (see Chapter 24).

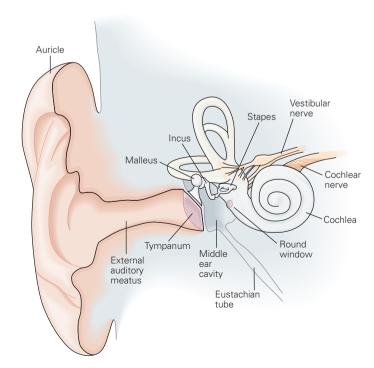

Hearing depends on the remarkable properties of hair cells, the receptors of the internal ear. Hair cells receive mechanical inputs that correspond to sounds and transduce these signals into electrical responses that are forwarded to the brain for interpretation. These cells can measure motions of atomic dimensions and transduce stimuli ranging from static inputs to those at frequencies of tens of kilohertz. Hair cells also serve as mechanical amplifiers that augment our auditory sensitivity. Each of the paired cochleas contains approximately 16,000 of these cells. Deterioration of hair cells accounts for most of the hearing loss that afflicts more than 30 million Americans.

The Ear Has Three Functional Parts

Sound consists of alternating compressions and rarefactions propagated by an elastic medium, the air, at a speed of approximately 340 m/s. As we are reminded on making the effort to shout, producing these pressure changes requires that work be done on the air by our vocal apparatus or some other sound source. Each of our ears must capture this mechanical energy, transmit it to the receptor organ, and transduce it into electrical signals suitable for neural analysis. These three tasks are the functions of, respectively, the external ear, the middle ear, and the inner ear (Figure 30–1).

The most obvious component of the human external ear is the auricle, a prominent fold of cartilage-supported skin. Much as a parabolic antenna collects

Figure 30–1 The structure of the human ear. The external ear, especially the prominent auricle, focuses sound into the external auditory meatus. Alternating increases and decreases in air pressure vibrate the tympanum. These vibrations are conveyed across the air-filled middle ear by three tiny, linked bones: the malleus, the incus, and the stapes. Vibration of the stapes stimulates the cochlea, the hearing organ of the inner ear.

electromagnetic radiation, the auricle acts as a reflector to capture sound efficiently and to focus it into the external auditory meatus, or ear canal. The external auditory meatus ends at the tympanum or eardrum, a thin diaphragm approximately 9 mm in diameter.

The external ear is not uniformly effective at capturing sound from any direction; the auricle's corrugated surface collects sounds best when they originate at different, but specific, positions with respect to the head. Our capacity to localize sounds in space, especially along the vertical axis, depends critically on the sound-gathering properties of the external ear.

The middle ear is an air-filled pouch connected to the pharynx by the Eustachian tube. Airborne sound traverses the middle ear as vibrations of three tiny ossicles, or bones: the malleus (hammer), incus (anvil), and stapes (stirrup). The base of the malleus is attached to the tympanic membrane; its other extreme makes a ligamentous connection to the incus, which is similarly connected to the stapes. The flattened termination of the stapes, the footplate, inserts in an opening—the oval window—in the bony covering of the cochlea. The first two ossicles are relics of evolution, for their antecedents served as components of the jaw in reptilian ancestors.

The inner ear, or cochlea (from the Greek *cochlos*, meaning snail), is a coiled structure of progressively diminishing diameter wound like a snail's shell around a conical bony core (Figure 30–1). It is approximately 9 mm across, the size of a chickpea. The cochlea is covered with a thin layer of laminar bone and embedded within the dense structure of the temporal bone. The inner and outer aspects of the cochlea's bony surface are lined with layers of connective tissue, the endosteum and periosteum.

The interior of the cochlea consists of three liquid-filled compartments termed *scalae* (Latin, meaning staircases). In a cross section of the cochlea at any position along its spiral course, the compartment farthest from the base is the *scala vestibuli* (Figure 30–2). At the basal end of this chamber is the oval window, an opening that is sealed by the footplate of the stapes. The chamber nearest the cochlear base is the *scala tympani*; it too has a basal aperture, the round window, which is closed by a thin, elastic diaphragm. The two chambers are separated along most of their length by the cochlear partition or duct. The scala vestibuli and scala tympani communicate with one another at the helicotrema, where the cochlear partition terminates slightly below the cochlear apex.

The third liquid-filled cavity, the *scala media*, lies within the cochlear partition. A pair of elastic structures separates the scala media from the other ducts

(Figure 30–2). The thin Reissner's membrane, or vestibular membrane, divides the scala media from the scala vestibuli. The basilar membrane separates the scala media from the subjacent scala tympani; it is a complex structure involved in auditory transduction.

Hearing Commences with the Capture of Sound Energy by the Ear

Psychophysical experiments have established that we perceive an approximately equal increment in loudness for each tenfold increase in the amplitude of a sound stimulus. This type of relation is characteristic of many of our senses and is the basis of the Weber-Fechner law (see Chapter 21). A logarithmic scale is therefore useful in relating quantitatively sound intensity to perceived loudness. The sound-pressure level, *L*, of any sound may be expressed in decibels as

$$L = 20 \cdot \log_{10}(P/P_{REF}),$$

in which P, the magnitude of the stimulus, is the root-mean-square sound pressure (in units of pascals, abbreviated Pa, or newtons per square meter). For a sinusoidal stimulus the amplitude exceeds the root-mean-square value by a factor of $\sqrt{2}$. The reference level on this scale, 0 dB, corresponds to a root-mean-square sound pressure, P_{REF} , of 20 μ Pa. This level represents the approximate threshold of human hearing at 1 to 4 kHz, the frequency range in which our ears are most sensitive.

That sound consists of alternating changes in the local air pressure is evident when a loud noise rattles a window. The loudest sound tolerable to humans, with an intensity of approximately 120 dB, transiently alters the local atmospheric pressure by only $\pm 0.01\%$. Acting on a window 1 m on each side, this oscillatory pressure nonetheless produces a force of ± 14 newtons. To rattle the same window by pushing upon it, we would need to exert a comparable force, approximately ± 3 lb. In contrast, a tone at the threshold level causes a fractional change in the local pressure of much less than one part in a billion.

Despite their small magnitude, sound-induced increases and decreases in air pressure push and pull effectively upon the tympanum, moving it inward and outward (Figure 30–3A, B). The subsequent motions of the ossicles are complex, depending on both the frequency and the intensity of sound. In simple terms, however, the actions of these bones may be understood as those of two interconnected levers (the malleus and incus) and a piston (the stapes). The vibration of the incus alternately drives the stapes deeper into the oval

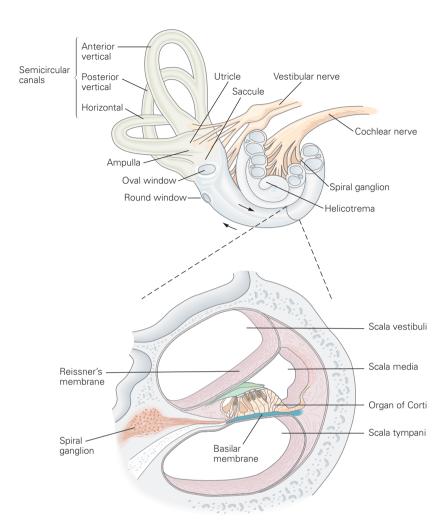

Figure 30-2 The structure of the cochlea.

A cross section of the cochlea shows the arrangement of the three liquid-filled ducts or scalae, each of which is approximately 33 mm long. The scala vestibuli and scala tympani communicate through the helicotrema at the apex of the cochlea. At the base each duct is closed by a sealed aperture. The scala vestibuli is closed by the oval window, against which the stapes pushes in response to sound; the scala tympani is closed by the round window, a thin, flexible membrane. Between these two compartments lies the scala media, an endolymph-filled tube whose epithelial lining includes the 16,000 hair cells in the organ of Corti surmounting the basilar membrane. The cross section in the lower diagram has been rotated so that the cochlear apex is oriented toward the top.

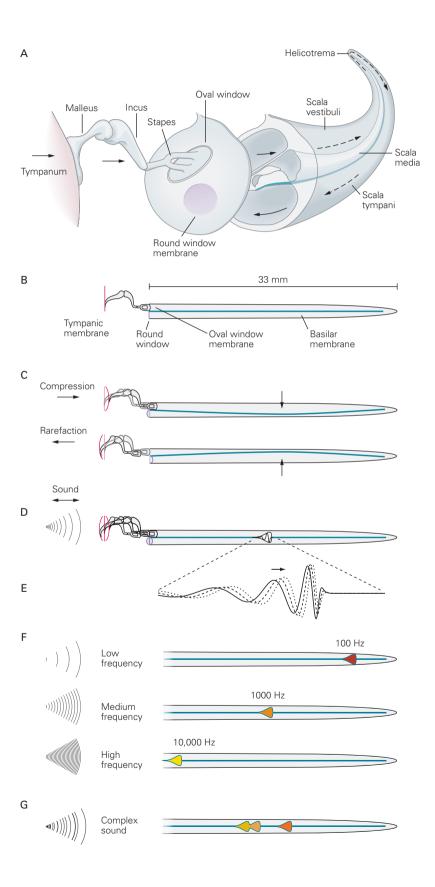

window and retracts it. The footplate of the stapes thus serves as a piston that pushes and pulls cyclically upon the liquid in the scala vestibuli. The overall effect of the middle ear is to match the impedance of the air outside the ear to that of the cochlear partition, thus ensuring the efficient transfer of sound energy from the first medium to the second.

The action of the stapes at the oval window produces changes in pressure that propagate throughout the liquid of the scala vestibuli at the speed of sound. Because the aqueous perilymph is virtually incompressible, however, the primary effect of the stapes's motion is to displace the liquid in the scala vestibuli in the one direction that is not restricted by a rigid boundary: toward the elastic cochlear partition (Figure 30–3B). The deflection of the cochlear partition downward increases the pressure in the scala tympani. The enhanced pressure displaces a liquid mass that causes outward bowing of the round window. Each cycle of

a sound stimulus thus evokes a cycle of up-and-down movement of a minuscule volume of liquid in each of the inner ear's three chambers.

Because the energy associated with acoustic signals is generally quite small, compromise of the middle ear's normal structure may lead to *conductive hearing loss*, of which two forms are especially common. First, scar tissue caused by middle-ear infection (otitis media) can immobilize the tympanum or ossicles. Second, a proliferation of bone in the ligamentous attachments of the ossicles can deprive the ossicles of their normal freedom of motion. This chronic condition of unknown origin, termed *otosclerosis*, can lead to severe deafness.

A clinician may test for conductive hearing loss by the simple Rinné test. A patient is asked to compare the loudness of a vibrating tuning fork held in the air near an affected ear with that perceived when the base of the tuning fork is pressed against the patient's head just

behind the auricle. If the latter stimulus is perceived to be louder, the patient's conductive pathway may be damaged but the internal ear is likely to be intact. In contrast, if bone conduction is not more efficient than airborne stimulation, the patient may have inner-ear damage, that is, sensorineural hearing loss. The diagnosis of conductive hearing loss is important because surgical intervention is highly effective: Removal of scar tissue or reconstitution of the conductive pathway with an inert prosthesis can in many instances restore excellent hearing.

The Hydrodynamic and Mechanical Apparatus of the Cochlea Delivers Mechanical Stimuli to the Receptor Cells

The Basilar Membrane Is a Mechanical Analyzer of Sound Frequency

The mechanical properties of the basilar membrane are key to the cochlea's operation. To appreciate this, suppose that the basilar membrane had uniform dimensions and mechanical properties along its entire length, approximately 33 mm. Under these conditions a fluctuating pressure difference between the scala vestibuli and the scala tympani would move the entire basilar membrane up and down with similar excursions at all points (Figure 30–3C).

This would occur regardless of the frequency of stimulation; any pressure difference between the scala vestibuli and the scala tympani would propagate throughout those chambers within microseconds, so the basilar membrane would be subjected to similar forces at any position along its length. This simple form of basilar-membrane motion in fact occurs in the auditory organs of some reptiles.

In reality, however, the mechanical properties of the mammalian basilar membrane vary continuously along the cochlea's length. The basilar membrane at the apex of the human cochlea is more than five times as broad as at the base. Thus, although the cochlear chambers become progressively larger from the organ's apex toward its base, the basilar membrane decreases in width. Moreover, the basilar membrane is

Figure 30–3 (Opposite) Motion of the basilar membrane.

A. An uncoiled cochlea, with its base displaced to show its relation to the scalae, indicates the flow of stimulus energy. Sound vibrates the tympanum, which sets the three ossicles of the middle ear in motion. The piston-like action of the stapes, a bone inserted partially into the elastic oval window, produces oscillatory pressure differences that rapidly propagate along the scala vestibuli and scala tympani. Low-frequency pressure differences are shunted through the helicotrema, where the two ducts communicate. The oval and round windows do not actually lie at the extreme base of the cochlea, but occur at oblique angles slightly toward the apex.

- **B.** The functional properties of the cochlea are conceptually simplified if the cochlea is viewed as a linear structure with only two liquid-filled compartments separated by the elastic basilar membrane.
- C. If the basilar membrane had uniform mechanical properties along its full extent, a compression would drive the tympanum and ossicles inward, increasing the pressure in the scala vestibuli and forcing the basilar membrane downward. Opposite movements would occur during a rarefaction. The pressure changes in the scala tympani are relieved by bowing of the round-window membrane. The movements of the tympanum, ossicles, and basilar membrane are greatly exaggerated.
- D. In fact, the basilar membrane's mechanical properties vary continuously along its length. The oscillatory stimulation of a sound causes a traveling wave on the basilar membrane, shown here within the envelope of maximal displacement over an entire cycle. The magnitude of movement is grossly exaggerated in the vertical direction; the loudest tolerable sounds

move the basilar membrane by only ±150 nm, a scaled distance less than one-hundredth the width of the lines representing the basilar membrane in these figures.

- E. An enlargement of the active region in D demonstrates the motion of the basilar membrane in response to stimulation with sound of a single frequency. The continuous curve depicts a traveling wave at one instant; the vertical scale of basilar-membrane deflection is exaggerated about one-millionfold. The dashed and dotted curves portray the traveling wave at successively later times as it progresses from the cochlear base (left) toward the apex (right). As the wave approaches the characteristic place for the stimulus frequency, it slows and grows in amplitude. The stimulus energy is then transferred to hair cells at the position of the wave's peak.
- F. Each frequency of stimulation excites maximal motion at a particular position along the basilar membrane. Low-frequency sounds produce basilar-membrane motion near the apex, where the membrane is relatively broad and flaccid. Mid-frequency sounds excite the membrane in its middle. The highest frequencies that we can hear excite the basilar membrane at its narrow, taut base. The mapping of sound frequency onto the basilar membrane is approximately logarithmic.
- G. The basilar membrane performs spectral analysis of complex sounds. In this example a sound with three prominent frequencies, such as the three formants of a vowel sound, excites basilar-membrane motion in three regions, each of which represents a particular frequency. Hair cells in the corresponding positions transduce the basilar-membrane oscillations into receptor potentials, which in turn excite the nerve fibers that innervate these particular regions.

relatively thin and floppy at the apex of the cochlea but thicker and tauter toward the base. Because its mechanical properties vary along its length, the basilar membrane does not oscillate like a single string on a musical instrument; instead, it more resembles a panoply of strings that vary from the coarsest string on a bass viol to the finest string on a violin.

Stimulation with a pure tone evokes a complex and elegant movement of the basilar membrane. Over one complete cycle of a sound, each affected segment along the basilar membrane undergoes a single cycle of vibration (Figure 30–3D, E). The various parts of the membrane do not, however, oscillate in phase with one another; instead, some portions of the membrane move upward while others move downward. As first demonstrated by Georg von Békésy using stroboscopic illumination, the overall pattern of motion of the membrane is that of successive traveling waves.

Because mechanical stimulation is applied at the cochlear base as a pressure difference between scala vestibuli and scala tympani, the traveling wave progresses from the cochlear base toward the apex. Each wave reaches its maximal amplitude at a particular position appropriate for the frequency of stimulation, then declines rapidly in size as it advances toward the cochlear apex. A traveling wave ascending the basilar membrane resembles an ocean wave rolling toward the shore: As the wave nears the beach its crest grows to a maximal height, then breaks and rapidly fades away.

Although the analogy of an ocean wave gives some sense of the appearance of the basilar membrane's motion, the connection between the cochlear traveling wave and the movement of an ocean wave is only metaphorical—the physical bases of the two waves are quite distinct. An ocean wave is the result of the momentum of a wind-blown mass of water. In contrast, movement of the basilar membrane is the result of motion of the liquid masses above and below the membrane. These liquids are continuously driven up and down by the energy supplied by the stapes's piston-like movements at the oval window.

The variation in the mechanical properties of the mammalian basilar membrane explains why the membrane is tuned to different frequencies at each point along its length. In humans the membrane at the apex of the cochlea responds best to the lowest audible frequencies, down to approximately 20 Hz. At the cochlear base it responds to frequencies as great as 20 kHz. The intervening frequencies are represented along the basilar membrane in a continuous array (Figure 30–3F). In the 19th century the German physiologist Hermann von Helmholtz was the first to appreciate that the

basilar membrane's operation is essentially the inverse of a piano's. The piano synthesizes a complex sound by combining the pure tones produced by numerous vibrating strings; the cochlea deconstructs a complex sound by isolating each component tone at a discrete segment of the basilar membrane.

The arrangement of vibration frequencies along the basilar membrane is an example of a *tonotopic map*. The relation between frequency and position on the basilar membrane varies smoothly and monotonically but is not linear. Instead, the logarithm of the best frequency is roughly proportional to the distance from the cochlea's apex. The frequencies from 20 Hz to 200 Hz, those between 200 Hz and 2 kHz, and those spanning 2 kHz to 20 kHz are each apportioned approximately one-third of the basilar membrane's extent.

Analysis of the response to a complex sound illustrates how the basilar membrane operates in daily life. A vowel sound in human speech, for example, ordinarily comprises three dominant frequency components termed formants. Measurement of the sound pressure outside an ear exposed to such a sound reveals a complex, seemingly chaotic signal. The movements of the tympanum and ossicles in response to a vowel sound likewise appear very complicated. The motion of the basilar membrane, however, is much simpler. Each frequency component of the stimulus establishes a traveling wave that, to a first approximation, is independent of the waves evoked by the others (Figure 30-3G). Each traveling wave reaches its peak excursion at a point on the basilar membrane appropriate for that frequency component. Moreover, the amplitude of each traveling wave is proportional, albeit in a complex way, to the intensity of the corresponding frequency component. The basilar membrane thus acts as a mechanical frequency analyzer by distributing specific stimulus energies to hair cells arrayed along its length, and in doing so begins the encoding of the frequencies and intensities in a sound.

The Organ of Corti Is the Site of Mechanoelectrical Transduction in the Cochlea

The organ of Corti, a ridge of epithelium extending along the basilar membrane, is the receptor organ of the inner ear. Each organ of Corti contains approximately 16,000 hair cells innervated by approximately 30,000 afferent nerve fibers, which carry information into the brain along the eighth cranial nerve. Like the basilar membrane itself, both the hair cells and the auditory nerve fibers are tonotopically organized: At any position along the basilar membrane the hair cells are most sensitive to a particular frequency, and these

frequencies are logarithmically mapped in ascending order from the cochlea's apex to its base.

The organ of Corti includes a variety of cells, many of obscure function, but four types have obvious importance. First, there are two varieties of hair cells. The *inner hair cells* form a single row of approximately 3,500 cells, whereas approximately 12,000 *outer hair cells* lie in three rows farther from the central axis of the cochlear spiral (Figure 30–4). The outer hair cells are

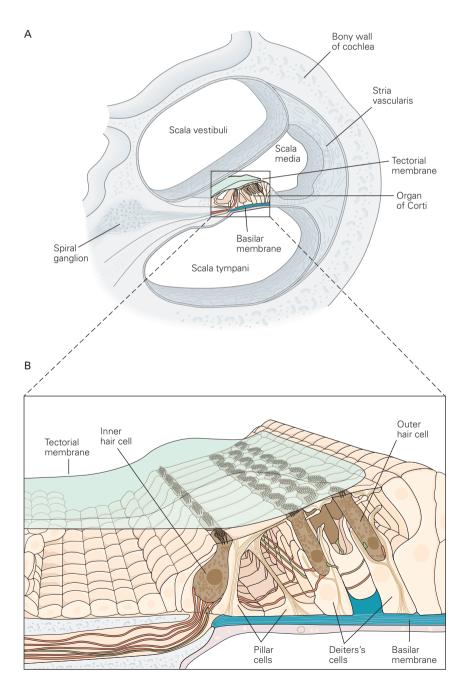

supported at their bases by the Deiters's (phalangeal) cells; the space between the inner and outer hair cells is delimited and mechanically supported by pillar cells.

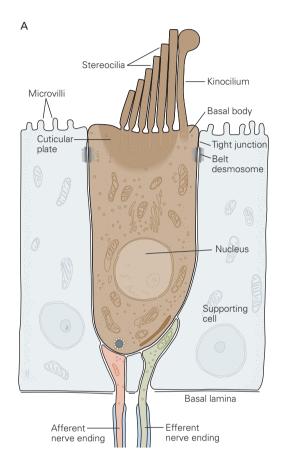

A second epithelial ridge adjacent to the organ of Corti, but nearer the cochlea's central axis, gives rise to the tectorial membrane, a cantilevered gelatinous shelf that covers the organ of Corti (Figure 30–4). The tectorial membrane is anchored at its base by the interdental cells, which are also partly responsible for secreting

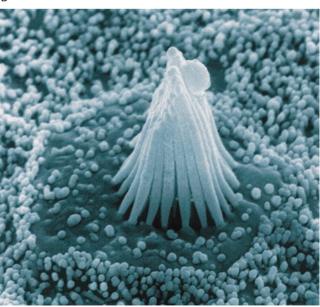

Figure 30–4 Cellular architecture of the human organ of Corti. Although there are differences among species, the basic plan is similar for all mammals.

A. The organ of Corti, the inner ear's receptor organ, is an epithelial strip that surmounts the elastic basilar membrane. The organ contains some 16,000 hair cells arrayed in four rows: a single row of inner hair cells and three rows of outer hair cells. The mechanically sensitive hair bundles of these receptor cells protrude into endolymph, the liquid within the scala media. Reissner's membrane, which provides the upper boundary of the scala media, separates the endolymph from the perilymph in the scala vestibuli. The hair bundles of outer hair cells are attached at their tops to the lower surface of the tectorial membrane, a gelatinous shelf that extends the full length of the basilar membrane.

B. The hair cells are separated and supported by pillar cells and Deiters's cells. One hair cell has been removed from the middle row of outer hair cells to reveal the three-dimensional relationship between supporting cells and hair cells. Efferent nerve endings at the bases of outer hair cells have been omitted from the drawing.

this extracellular structure. The tectorial membrane's tapered distal edge forms a fragile connection with the organ of Corti. When the basilar membrane vibrates in response to a sound, the organ of Corti and the overlying tectorial membrane move with it. Because the basilar and tectorial membranes pivot about different lines of insertion, their up-and-down motion is accompanied by back-and-forth shearing motion of the upper surface of the organ of Corti and the lower surface of the tectorial membrane. This motion is detected by hair cells.

Hair cells originate from the surface ectoderm of the embryo and retain an epithelial character. Columnar or flask-shaped, a hair cell lacks both dendrites and an axon (Figure 30–5A). Around its apex the hair cell is connected to nonsensory supporting cells. A special saline solution, the endolymph, bathes the cell's apical aspect. A tight junction separates this liquid from the ordinary extracellular fluid, or perilymph, that contacts the basolateral surface of the cell. Immediately below the tight junction an intermediate junction provides a strong mechanical attachment for the hair cell.

The hair bundle, which serves as a receptor for mechanical stimuli, projects from the flattened apical surface of the hair cell. Cochlear hair bundles comprise a few hundred cylindrical processes, the *stereocilia*, arranged in a hexagonal array and extending several micrometers from the cell surface. Because successive stereocilia across a cell's surface vary in length, a hair bundle is beveled like the tip of a hypodermic needle (Figure 30–5B). In the mammalian cochlea the inner hair cell bundles have a roughly linear cross-sectional form. Outer hair cell bundles, in contrast, have a V shape (Figure 30–6).

Figure 30-5 Structure of a vertebrate hair cell.

A. The epithelial character of the hair cell is evident in this drawing of the sensory epithelium from a frog's internal ear. The cylindrical hair cell is joined to adjacent supporting cells by a junctional complex around its apex. The hair bundle, a mechanically sensitive organelle, extends from the cell's apical surface. The bundle comprises some 60 stereocilia arranged in stepped rows of varying length. At the bundle's tall edge stands the single kinocilium, an axonemal structure with a bulbous swelling at its tip; in the mammalian cochlea this organelle degenerates around the time of birth. Deflection of the hair bundle's top to the right depolarizes the hair cell; movement in the opposite direction elicits hyperpolarization. The hair cell is surrounded by supporting cells, whose apical surfaces bear a stubble of microvilli. Afferent and efferent synapses contact the basolateral surface of the plasma membrane.

B. This scanning electron micrograph of a hair cell's apical surface reveals the hair bundle protruding approximately 8 μ m into the endolymph.

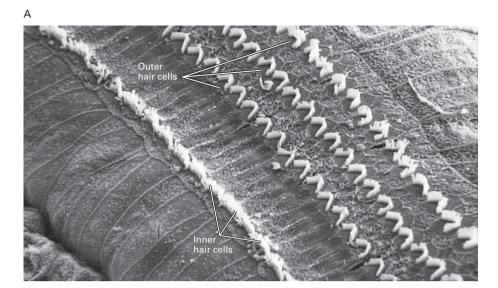

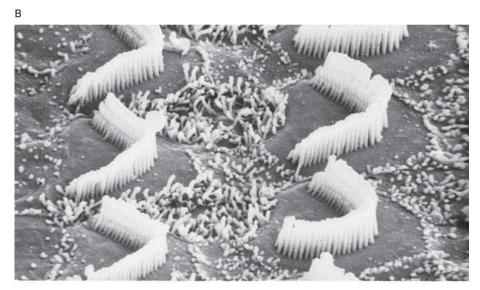

Figure 30–6 Arrangement of the hair cells in the organ of Corti.

A. Inner hair cells form a single row, and the stereocilia of each cell are arranged linearly. In contrast, outer hair cells are distributed in three rows, and the stereocilia of each cell are arranged in a V configuration. The apical surfaces of several other cells are visible: inner spiral sulcus cells, pillar cells, Deiters's cells, and Hensen's cells.

B. Higher magnification shows more clearly the V-shaped configuration of the hair bundle atop each outer hair cell. The hair-cell surface around the stereocilia is smooth, whereas the surfaces of supporting cells are endowed with microvilli.

Each stereocilium is a rigid cylinder whose cytoskeleton consists of a fascicle of actin filaments cross-linked by the proteins plastin (fimbrin), fascin, and espin. Cross-linking renders a stereocilium much more rigid than would be expected for a bundle of unconnected actin filaments. The core of the stereocilium is covered by a tubular sheath of plasma membrane. Although a stereocilium is of constant diameter along most of its length, it tapers over the micrometer or so just above its basal insertion. As the stereocilium narrows from approximately 0.4 μm to one-quarter that diameter, the number of actin filaments diminishes from several hundred to only a few dozen. This thin cluster of microfilaments anchors the stereocilium in

the cuticular plate, a thick mesh of interlinked actin filaments lying beneath the cell membrane. Because of this tapered structure, a mechanical force applied at the stereocilium's tip causes the process to pivot around its basal insertion. Horizontal top connectors, extracellular filaments that interconnect adjacent stereocilia along each of the hair bundle's hexagonal axes, cause the bundle to move as a unit during stimulation at low frequencies. At high frequencies, the viscosity of the liquid between the stereocilia opposes their separation and again results in unitary motion of the hair bundle.

During its development every hair bundle includes at its tall edge a single true cilium, the *kinocilium*.

This structure possesses at its core an axoneme, or array of nine paired microtubules, and sometimes an additional central pair of microtubules. The kinocilium is not essential for mechanoelectrical transduction, for in mammalian cochlear hair cells it degenerates around the time of birth.

Hair Cells Transform Mechanical Energy into Neural Signals

Deflection of the Hair Bundle Initiates Mechanoelectrical Transduction

Just as in the human vestibular organs (see Chapter 40), mechanical deflection of the hair bundle is the stimulus that excites hair cells of the cochlea. A mechanical stimulus to a hair bundle elicits an electrical response, the receptor potential, by gating mechanically sensitive ion channels. In vitro, when a bundle is deflected by a probe attached near its top, the hair cell's response depends on the direction and magnitude of the stimulus.

In an unstimulated cell approximately 10% of the channels involved in stimulus transduction are open. As a result, the cell's resting potential, approximately –60 mV, is determined in part by the influx of cations through these channels. A stimulus that displaces the bundle toward its tall edge opens additional channels, thereby depolarizing the cell (Figure 30–7). In contrast, a stimulus that displaces the bundle toward its short edge shuts those transduction channels that are open at rest, thus hyperpolarizing the cell.

Hair cells respond only to stimuli parallel to the hair bundle's axis of morphological symmetry: Stimuli at right angles to the axis produce no change from the

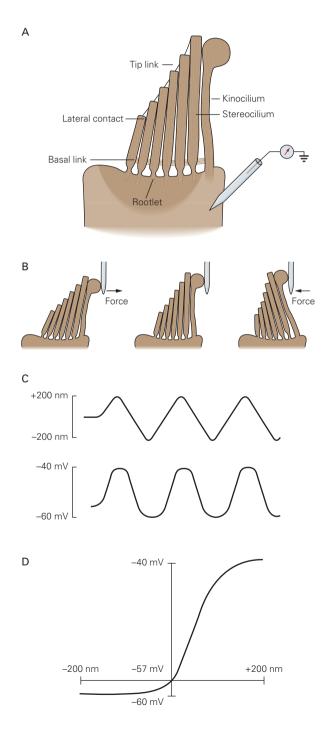

Figure 30-7 Mechanical sensitivity of a hair cell.

A. A recording electrode is inserted into a hair cell.

- **B.** A probe attached to the bulbous tip of the stereocilium is moved by a piezoelectric stimulator, deflecting the elastic hair bundle from its resting position. The actual deflections are generally only one-tenth as large as those portrayed.
- C. When the top of a hair bundle is displaced back-and-forth (upper trace), the opening and closing of mechanically sensitive ion channels produces an oscillatory receptor potential (lower trace) that may saturate in both the depolarizing and the hyperpolarizing directions.
- D. The relation between hair-bundle deflection (abscissa) and receptor potential (ordinate) is sigmoidal. The entire operating range is only approximately 100 nm, less than the diameter of an individual stereocilium.

resting potential. An oblique stimulus elicits a response proportional to its vectorial projection along the axis of sensitivity.

A hair cell's receptor potential is graded. As the stimulus amplitude increases, the receptor potential grows progressively larger up to the point of saturation.

The receptor potential of an inner hair cell can be as great as $25\,\text{mV}$ in peak-to-peak magnitude. The relation between a bundle's deflection and the resulting electrical response is sigmoidal (Figure 30–7D). A displacement of only $\pm 100\,\text{nm}$ represents approximately 90% of the response range. During normal stimulation a hair bundle moves through an angle of ± 1 degree or so, that is, by much less than the diameter of one stereocilium.

Hair cells are so sensitive that their response threshold is probably set by brownian motion; still weaker stimuli are lost in the thermal clatter of the ear's components. When observed in vitro a hair bundle exhibits brownian motion of approximately ± 3 nm. However, because the auditory system averages responses over several cycles to improve its signal-to-noise ratio, the threshold of hearing corresponds to hair-bundle deflection of as little as ± 0.3 nm. A stimulus of this magnitude evokes a receptor potential near $100~\mu V$ in amplitude.

The ion channels in hair cells that are involved in stimulus transduction are relatively nonselective, cation-passing pores with a conductance near 100 pS. Because small organic cations can support measurable current, and small fluorescent molecules can traverse the channel, the transduction channel's pore is about 1.3 nm in diameter. Most of the transduction current is carried by K⁺, the cation with the highest concentration in the endolymph bathing the hair bundle.

The large diameter and poor selectivity of the pore permit transduction channels to be blocked by aminoglycoside antibiotics, such as streptomycin, gentamicin, and tobramycin. When used in large doses to counter bacterial infections, these drugs have a toxic effect on hair cells; the antibiotics damage hair bundles and eventually kill hair cells. These drugs evidently insinuate themselves through transduction channels at a low rate and thus cause long-term toxic effects by interfering with protein synthesis on the mitochondrial ribosomes, which resemble prokaryotic ribosomes. Consistent with this hypothesis, human sensitivity to aminoglycosides is maternally inherited and in many instances reflects a single base change in the 12S ribosomal RNA gene of the mitochondrion.

Single-channel recordings and noise analysis suggest that each hair cell possesses only a few hundred transduction channels. Because the number of channels is about the same as the number of stereocilia in a hair bundle and because the magnitude of the receptor potential is roughly proportional to the number of stereocilia remaining in a microdissected bundle, there are probably only two active transduction channels per stereocilium. The paucity of channels along with the lack of high-affinity ligands with which to label them explains why the biochemical identity of

the transduction channels remains uncertain. Genetic and physiological evidence suggests, however, that proteins of the transmembrane channel family, specifically TMC1 and TMC2, are involved in mechanoelectrical transduction.

Mechanical Force Directly Opens Transduction Channels

The mechanism for gating of transduction channels in hair cells differs fundamentally from the mechanisms used for such electrical signals as the action potential or postsynaptic potential. Many ion channels respond to changes in membrane potential or to specific ligands (see Chapters 5, 7, 9–11). In contrast, the mechanoelectrical transduction channels in the hair cell are activated by mechanical strain.

Two lines of evidence suggest that the opening and closing of transduction channels is regulated by tension in elastic structures within the hair bundle. First, a bundle is stiffer along its axis of morphological symmetry, and hence of mechanical sensitivity, than at a right angle. This observation suggests that a portion of the work done in deflecting a bundle goes into elastic elements, termed gating springs, that pull on the molecular gates of the transduction channels. Because the gating springs contribute over half of a hair bundle's stiffness, the transduction channels efficiently capture the energy supplied when a bundle is deflected. In addition, hair-bundle stiffness decreases during channel gating, a phenomenon expected if the channels are gated directly through a mechanical linkage to the hair bundle.

A second indication that transduction channels are directly controlled by gating springs is the rapidity with which hair cells respond. The response latency is so brief, only a few microseconds, that gating is more likely to be direct than to involve a second messenger (see Chapter 11). Moreover, the electrical responses of hair cells to a series of step stimuli of increasing magnitude become successively larger and faster. This behavior favors a kinetic scheme in which mechanical force controls the rate constant for channel gating. If the mechanical energy from a stimulus is stored in a spring attached to the channel's gate, the rates of channel opening and closing are determined by the probability that the stored energy of the spring exceeds the transition-state energy for channel gating.

Mechanoelectrical transduction occurs near the tips of the stereocilia, as demonstrated by three experimental techniques. First, the region where cations flow into a hair cell was inferred by measuring small differences in the extracellular potential around a stimulated hair bundle. The voltage signal is strongest at the bundle's top; cations flowing toward transduction channels converge near the stereociliary tips. Second, aminoglycoside antibiotics, which block these channels, have their greatest effect when applied from a microelectrode directed at the top of the hair bundle. Finally, Ca²⁺-sensitive fluorescent indicators initially signal Ca²⁺ entry near the apex of a deflected hair bundle. Measurements from cochlear hair cells at high temporal resolution suggest that the channels occur precisely at the stereociliary tips. When transduction current enters the channels, the ensuing change in membrane potential must propagate axially down the stereocilia before it changes the potential at the base of the cell body and thus influences the rate of transmitter release. Because the stereocilia are short, however, their cable properties do not attenuate electrical signals significantly.

The *tip link* is a probable component of the gating spring. A tip link is a fine molecular braid joining the distal end of one stereocilium to the side of the longest adjacent process (Figure 30–8A). The upper two-thirds of the link consists of a parallel homodimer of cadherin-23 molecules; the lower third represents a parallel homodimer of protocadherin-15 chains. The two components are joined at their tips in a Ca²⁺-sensitive manner. It is thought that each link is attached, probably at its lower end, to the molecular gates of two transduction channels. Deflection of a hair bundle toward its tall edge tenses the tip link and promotes channel opening; movement in the opposite direction slackens the link and allows the associated channels to close (Figure 30–8B).

Three experimental results suggest that the tip links are components of the gating springs. First, tip links are universal features of hair bundles and are situated at the site of transduction inferred from biophysical experiments. Second, the orientation of the links is consistent with the vectorial sensitivity of transduction. The links invariably interconnect stereocilia in a direction parallel with the hair bundle's plane of mirror symmetry. Stimulation at a right angle to the bundle's plane of symmetry, which would not be expected to alter the length of the links, elicits little or no response from a hair cell. Finally, when tip links are destroyed by exposing hair cells to Ca²⁺ chelators, transduction vanishes. As the tip links regenerate over the course of approximately 12 hours, a hair cell regains mechanosensitivity. It remains unclear whether the elasticity of gating springs resides primarily in the tip links or in the structures at their two insertions.

In the mammalian cochlea hair bundles are deflected through their linkage to the tectorial membrane. As the basilar membrane oscillates up and down, carrying the hair cells with it, a shearing motion occurs between the organ of Corti and the overlying tectorial membrane (Figure 30–9). The hair bundles of outer hair cells, whose tips are firmly attached to the tectorial membrane, are directly deflected by this movement. The hair bundles of inner hair cells, which do not contact the tectorial membrane, are deflected by movement of the liquid beneath the membrane. This mode of stimulation affords some mechanical amplification of the signals reaching hair bundles. At least for high-frequency stimuli, the movements of hair bundles are thought to be severalfold greater than that of the basilar membrane.

Direct Mechanoelectrical Transduction Is Rapid

In contrast to hair cells, many other sensory receptors, such as photoreceptors and olfactory neurons, use cyclic nucleotides or other second messengers in stimulus transduction. This strategy is advantageous in that the enzymatic pathway that generates a second messenger amplifies the signal, and feedback within the metabolic pathway readily permits adaptation and desensitization (see Chapter 11).

What is the advantage of transduction without the intervention of a second messenger? The answer probably lies in its speed. Hair cells operate much more quickly than do other sensory receptor cells of the vertebrate nervous system, and indeed more quickly than neurons themselves. To deal with the frequencies of biologically relevant sounds, transduction by hair cells must be rapid. Given the behavior of sound in air and the dimensions of sound-emitting and sound-absorbing organs such as vocal cords and eardrums, optimal auditory communication occurs in the frequency range of 10 Hz to 100 kHz. Much higher frequencies propagate poorly through air; much lower frequencies are inefficiently produced and captured by animals of moderate size.

Locating sound sources, one of the most important functions of hearing, sets even more stringent limits on the speed of transduction. A sound from a source directly to one side of a person reaches the nearer ear somewhat sooner than the farther. Although this delay is at most 700 μs , a human observer can locate sound sources on the basis of much smaller delays, about 10 μs . For this to occur, hair cells must be capable of detecting acoustic waveforms with microsecond-level resolution.

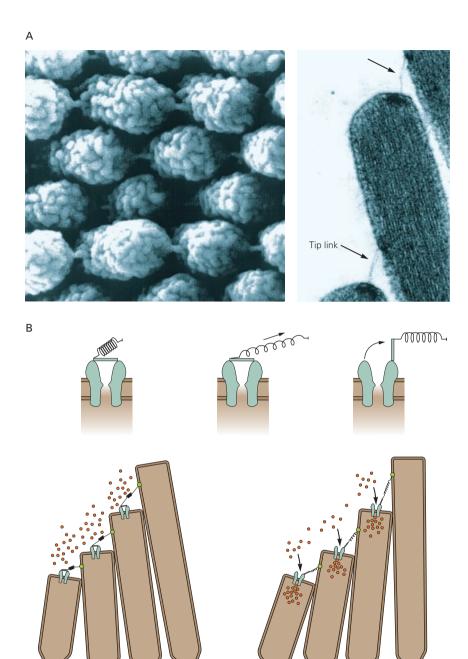

The ability of hair cells to discriminate high frequencies of stimulation implies that transduction channels are gated very rapidly. Even in animals sensitive

Figure 30–8 Mechanoelectrical transduction by hair cells.

A. A tip link connects each stereocilium to the side of the longest adjacent stereocilium, as seen in a scanning electron micrograph (left) and a transmission electron micrograph (right) of a hair bundle's top surface. Each tip link is only 3 nm in diameter. The links appear stouter in the illustration on the left because of metallic coating during specimen preparation. (Reproduced, with permission, from Assad, Shepherd, and Corey 1991; reproduced, with permission, from Hudspeth and Gillespie 1994.)

B. Top: Ion flux through the channel that underlies mechanoelectrical transduction in hair cells is regulated by a molecular gate. The opening and closing of the gate are controlled by the tension in an elastic element, the gating spring, that senses hair-bundle displacement. (Adapted, with permission, from Howard and Hudspeth 1988.)

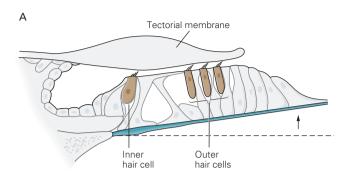

Bottom: When the hair bundle is at rest each transduction channel clatters between closed and open states, spending most of its time shut. Displacement of the bundle in the positive direction increases the tension in the gating spring, here assumed to be in part a tip link, attached to each channel's molecular gate. The enhanced tension promotes channel opening and the influx of cations, thereby producing a depolarizing receptor potential. (Adapted, with permission, from Hudspeth 1989.)

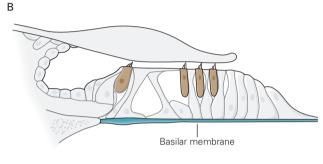

to relatively low frequencies, the response to a stimulus of moderate intensity has a time constant of only $80~\mu s$ at room temperature. For mammals to be able to respond to frequencies greater than 100~kHz, the hair cells evidently display gating rates that are an order of magnitude greater.

The Temporal Responsiveness of Hair Cells Determines Their Sensitivity

The mechanical sensitivity of hair cells is not constant; responsiveness varies in such a way that a given cell best detects behaviorally relevant stimuli. When it is

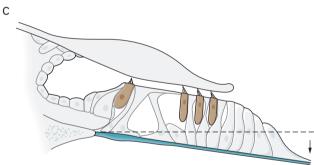

Figure 30–9 Forces acting on cochlear hair cells. Hair cells in the cochlea are stimulated when the basilar membrane is driven up and down by differences in the pressure between the scala vestibuli and scala tympani. This motion is accompanied by shearing movements between the tectorial membrane and organ of Corti. These motions deflect the hair bundles of outer hair cells, which are attached to the lower surface of the tectorial membrane. The hair bundles of inner hair cells, which are not attached to the tectorial membrane, are deflected by the movement of liquid in the space beneath that structure. In both instances the deflection initiates mechanoelectrical transduction of the stimulus.

A. When the basilar membrane is driven upward, shear between the hair cells and the tectorial membrane deflects hair bundles in the excitatory direction, toward their tall edge.

B. At the midpoint of an oscillation the hair bundles resume their resting position.

C. When the basilar membrane moves downward, the hair bundles are driven in the inhibitory direction.

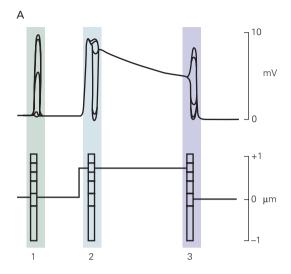

appropriate that low-frequency inputs be disregarded, hair cells possess a unique mechanism of adaptation that acts as a high-pass filter. In addition, many hair cells in auditory systems display electrical resonance that tunes them to specific frequencies of stimulation. Finally, hair cells employ mechanical amplification that enhances and further tunes their mechanosensitivity.

Hair Cells Adapt to Sustained Stimulation

Despite the precision with which a hair bundle grows, it cannot develop in such a way that the sensitive transduction apparatus is perfectly poised at its position of greatest mechanosensitivity. Some mechanism must compensate for developmental irregularities, as well as for environmental changes, by adjusting the gating springs so that transduction channels are active at the bundle's resting position. An adaptation process that continuously resets the hair bundle's range of mechanical sensitivity does just that. Because of adaptation, a hair cell can maintain a high sensitivity to transient stimuli while rejecting static inputs a million times as large.

Adaptation manifests itself as a progressive decrease in the receptor potential during protracted deflection of the hair bundle (Figure 30–10). The process is not one of desensitization, for the sensitivity of the receptor persists. However, with prolonged stimulation the sensitivity shifts from that of the bundle's resting point to approximately 80% of its deflected position. Adaptation occurs on a time scale three orders of magnitude slower than mechanoelectrical transduction: The time constant of adaptation is approximately 20 ms when endolymph bathes the hair bundle. The rate and extent of adaptation increase with increasing concentration of Ca²⁺ in the liquid contacting the apical cell surface.

How does adaptation occur? Because the mechanical force exerted by a hair bundle changes as adaptation proceeds, the process evidently involves an adjustment in the tension borne by the gating springs. It appears likely that the structure anchoring the upper end of each tip link, the insertional plaque, is repositioned during adaptation by an active molecular motor. Hair bundles contain at least five isoforms of myosin, the motor molecule associated with motility along actin filaments (see Chapter 34). Immunohistochemical studies indicate that myosin-1c occurs in clusters at insertional plaques and near the stereociliary tips, and site-directed mutagenesis implicates this isozyme in adaptation. Several dozen such myosin molecules associated with each tip link are thought to maintain tension by ascending cytoskeletal actin filaments and pulling the link's insertion with them (Figure 30–11).

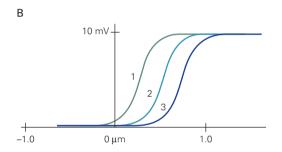

Figure 30–10 Adaptation of mechanoelectrical transduction in hair cells.

A. The lower trace shows mechanical test stimuli of various sizes applied before prolonged (100 ms) deflection of a hair bundle (1) and at two times during the deflection (2, 3). As shown in the upper trace, the rapid depolarization at the onset of the deflection is followed by a gradual decline toward a plateau. Seven records, each with a different test stimulus, are superimposed.

B. Adaptation alters the relation between hair-bundle displacement and the receptor potential of the hair cell before and during displacement. Each of the three curves is generated by plotting the electrical responses to the seven test stimuli against the respective hair-bundle displacements. As adaptation proceeds the sigmoidal relation shifts to the right along the abscissa without substantial changes in the curve's shape or amplitude. This result implies that during adaptation to a protracted stimulus a hair bundle's range of mechanical sensitivity approaches the position at which the bundle is held.

When a stimulus step increases the tension in a gating spring, the associated transduction channel opens, permitting an influx of cations. As Ca²⁺ ions accumulate in the stereociliary cytoplasm, they bind to the calmodulin light chains that adorn the neck

region of myosin-1c. The activation of calmodulin in turn reduces the upward force of the myosin-1c molecule, thereby shortening the gating spring. When the spring reaches its resting tension, closure of the channel reduces the Ca²⁺ influx to its original level, restoring a balance between the upward force of myosin and the downward tension in the spring.

Hair Cells Are Tuned to Specific Stimulus Frequencies

As a result of the tonotopic arrangement of the mammalian basilar membrane, every cochlear hair cell is most sensitive to stimulation at a specific frequency, termed its characteristic, natural, or best frequency. On average, the characteristic frequencies of adjacent inner hair cells differ by approximately 0.2%; adjacent piano strings, in comparison, are tuned to frequencies some 6% apart.

The sensitivity of a cochlear hair cell extends within a limited range above and below its characteristic frequency. This follows from the fact that the traveling wave evoked even by a pure sinusoidal stimulus spreads somewhat along the basilar membrane. The traveling wave of a stimulus tone with a pitch lower than the characteristic frequency of a particular hair cell passes that cell and peaks somewhat farther up the cochlear spiral. A higher-pitched tone causes a traveling wave that crests below the cell. Nevertheless, in either instance the basilar membrane undergoes some motion at the hair cell's site, so that the cell responds to the stimulus.

The frequency sensitivity of a hair cell may be displayed as a tuning curve. To construct a tuning curve, an experimenter stimulates the ear with pure tones at numerous frequencies below, at, and above the cell's characteristic frequency. The intensity of stimulation is adjusted for each frequency until the response reaches a predefined criterion magnitude. An investigator might, for example, ask what stimulus intensity is necessary at each frequency to produce a receptor potential 1 mV in peak-to-peak magnitude. The tuning curve is then a graph of sound level, presented logarithmically in decibels sound-pressure level, against stimulus frequency.

The tuning curve for an inner hair cell is typically V-shaped (Figure 30–12). The curve's tip represents the cell's characteristic frequency, the frequency that produces the criterion response for the lowest-intensity stimulus. Sounds of greater or lesser frequencies require higher intensities to excite the cell to the criterion response. As a consequence of the traveling

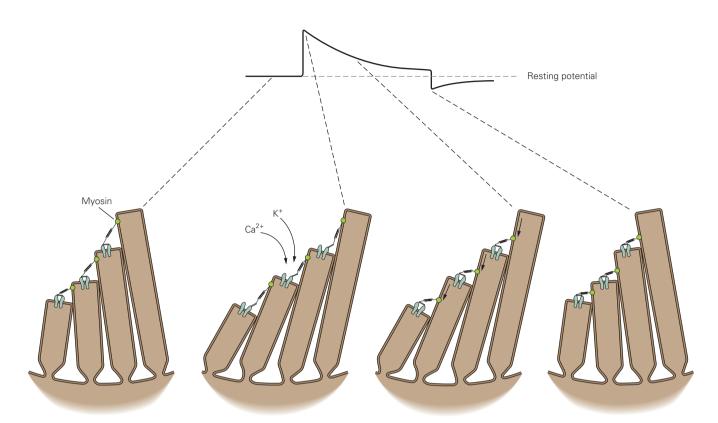

Figure 30–11 A model of adaptation by hair cells. Prolonged deflection of the hair bundle in the positive direction elicits an initial depolarization followed by a decline to a plateau and an undershoot at the cessation of the stimulus. Initially the stimulation increases tension in the tip link, thus opening transduction channels. As stimulation continues, however, a tip link's upper attachment is thought to slide down the stereocilium,

allowing each channel to close during adaptation. Prolonged deflection of the hair bundle in the negative direction elicits a complementary response. The cell is slightly hyperpolarized at first but shows a rebound depolarization at the end of stimulation; tension is restored to the initially slack tip link as myosin molecules actively pull up the link's upper insertion.

wave's shape, the slope of a tuning curve is far steeper on its high-frequency flank than on its low-frequency flank.

Hair cells must contend with acoustic stimuli that have a very low energy content. If the stimulus consists of a periodic signal, such as the sinusoidal pressure of a pure tone, a detection system can increase the signal-to-noise ratio by enhancing selectively the response to a relevant frequency. At least two cellular mechanisms are known to accomplish this task, thereby supplementing the tuning accomplished by the basilar membrane.

First, the mechanical properties of a hair bundle help tune it to a particular frequency, in the same way a tuning fork's resonant frequency depends on the mechanical properties of its tines. These properties include the bundle's flexibility and mass. The flexible elements that restore a bundle to its resting upright position are the gating springs and the actin-filled rootlets at the base of the stereocilia. Because the bundle moves through a viscous medium, the mass relevant to the bundle's tuning includes that of a volume of water dragged along by the moving bundle. Viscosity also heavily dampens the motion.

In the auditory organs of many animals the lengths of the hair bundles vary systematically along the tonotopic axis. Hair cells that respond to low-frequency acoustic stimuli have the longest bundles, whereas those that respond to the highest-frequency signals bear the shortest bundles. In the human cochlea, for example, an inner hair cell with a characteristic frequency of 20 kHz bears a 4 μ m hair bundle. At the opposite extreme, a cell sensitive to a 20 Hz stimulus has a bundle more than 7 μ m high.

Computer modeling shows that the tuning-fork mechanism helps to tune cochlear hair cells with

freestanding hair bundles, those that are not attached to a tectorial membrane. In humans these cells are the inner hair cells, the receptors that provide most of the information conveyed by the cochlear nerve. The length of the stereocilia may also affect the tuning of cells whose hair bundles are inserted into a tectorial membrane, for in these hair cells too there is an inverse relation between bundle length and characteristic frequency.

The second mechanism that tunes individual hair cells to specific frequencies is electrical in nature. In many fishes, amphibians, and reptiles including birds the membrane potential of each hair cell resonates at a particular frequency in response to an injected current pulse (Figure 30–13A). When a cell is stimulated with sounds of various frequencies but constant amplitude, it responds over a broad range of frequencies. However, when current is injected the cell responds most

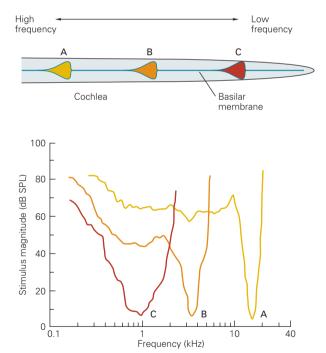

Figure 30–12 Tuning curves for cochlear hair cells. To construct a curve the experimenter presents sound at several frequencies. At each frequency the stimulus intensity is adjusted until the cell produces a criterion response, here 1 mV. The curve thus reflects the threshold of the cell for stimulation at a range of frequencies. Each cell is most sensitive to a specific frequency, its characteristic frequency. The threshold rises briskly—the sensitivity falls abruptly—as the stimulus frequency is raised or lowered. (Reproduced, with permission, from Pickles 1988.)

strongly to stimulation at the particular frequency at which the cell's membrane potential resonates. Whether electrical resonance contributes to frequency tuning in the ears of mammals, including humans, remains uncertain.

The basis of electrical resonance has been determined by voltage-clamp recordings from isolated hair cells. The depolarizing phase of an oscillation is driven by current carried into the cell through voltage-gated Ca²⁺ channels, whereas the repolarizing component results primarily from outward current through Ca2+sensitive K⁺ channels (Figure 30–13B). Several factors establish the frequency and sharpness of the resonance, including the membrane capacitance, the numbers of Ca²⁺ and K⁺ channels, and the time course of Ca²⁺ removal. In addition, variation in the K⁺ channels along the cochlea is a factor in the differences in frequency selectivity of the hair cells. Alternative splicing of the mRNA encoding cochlear K⁺ channels generates several channel isoforms that differ in their kinetics and their sensitivities to Ca²⁺ and voltage. Moreover, expression of the channel's auxiliary β subunit, which also regulates gating kinetics, displays a gradient along the tonotopic axis. How hair cells become tuned to their characteristic frequencies during development remains to be determined.

Sound Energy Is Mechanically Amplified in the Cochlea

The inner ear faces an important obstacle to efficient operation: A large portion of the energy in an acoustic stimulus goes into overcoming the damping effects of cochlear liquids on basilar-membrane motion rather than into excitation of hair cells. The sensitivity of the cochlea is too great, and auditory frequency selectivity too sharp, to result solely from the inner ear's passive mechanical properties. The cochlea must therefore possess some means of actively amplifying sound energy.

One indication that amplification occurs in the cochlea comes from measurements of the basilar membrane's movements with sensitive laser interferometers. In a preparation stimulated with low-intensity sound the motion of the membrane at any point is highly sensitive to frequency. As the sound intensity is increased, however, the membrane's sensitivity declines precipitously and its tuning becomes less sharp: The sensitivity of basilar-membrane motion to stimulation at 80 dB is less than 1% that for 10 dB excitation. The sensitivity predicted in modeling studies of a passive cochlea corresponds to that observed with high-intensity

Α

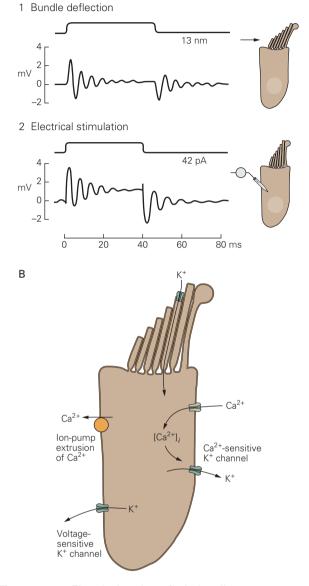

Figure 30-13 Electrical tuning of a hair cell.

A. 1. When the hair bundle is deflected, this hair cell's membrane potential oscillates at a frequency of approximately 180 Hz. 2. Passing electrical current into the same hair cell through a microelectrode evokes oscillation of the membrane potential at a similar frequency, an indication that the cell is tuned to a specific stimulus frequency by an electrical resonator. (Reproduced, with permission, from Crawford and Fettiplace 1981.)

B. A model of electrical resonance in a hair cell. Positive deflection of the hair bundle opens mechanoelectrical transduction channels in the stereocilia, thus depolarizing the cell. The depolarization opens voltage-sensitive Ca^{2+} channels, and the resulting Ca^{2+} influx augments the depolarization. As Ca^{2+} accumulates in the cytoplasm, however, it activates Ca^{2+} -sensitive K^+ channels that, along with voltage-sensitive K^+ channels, allow K^+ efflux that repolarizes the cell. To maintain an appropriate cytoplasmic Ca^{2+} concentration the Ca^{2+} must be sequestered and eventually pumped from the cell.

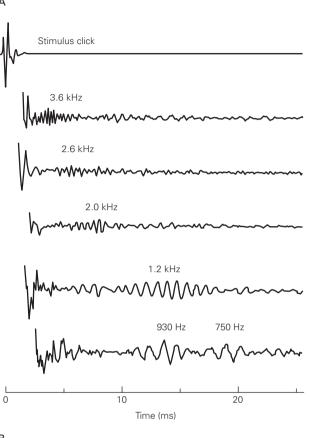

stimuli. This result implies that the motion of the basilar membrane is augmented more than 100-fold during low-intensity stimulation but that amplification diminishes progressively as the stimulus grows in strength.

In addition to this circumstantial evidence, experimental observations support the idea that the cochlea contains a mechanical amplifier. When a normal human ear is stimulated with a click, that ear emits one to several measurable pulses of sound. Each pulse includes sound in a restricted frequency band. High-frequency sounds are emitted with the shortest latency, approximately 5 ms, whereas low-frequency emissions occur after a delay as great as 20 ms (Figure 30–14A). These so-called *evoked otoacoustic emissions* are not simply echoes; they represent the emission of mechanical energy by the cochlea, triggered by acoustic stimulation.

A still more compelling manifestation of the cochlea's active amplification is spontaneous otoacoustic emission. When a suitably sensitive microphone is used to measure sound pressure in the ear canals of subjects in a quiet environment, at least 70% of normal human ears continuously emit one or more pure tones (Figure 30–14B). Although these sounds are generally too faint to be directly audible by others, physicians have reported hearing sounds emanating from the ears of newborns! The ears of adults, too, occasionally emit audible sounds. The active process in the cochlea ordinarily serves to counter the viscous damping effects of cochlear fluids on the basilar membrane. However, if this cochlear amplifier is overly active the ear emits sound, just as a public-address system howls when its gain is excessive.

What is the source of evoked and spontaneous otoacoustic emissions, and presumably of cochlear amplification as well? Several lines of evidence implicate outer hair cells as the elements that enhance cochlear sensitivity and frequency selectivity and hence as the energy sources for amplification. The afferent nerve fibers that extensively innervate the inner hair cells make only minimal contacts with the outer hair cells. Instead, the outer hair cells receive an extensive efferent innervation that, when activated, decreases cochlear sensitivity and frequency discrimination. Pharmacological ablation of outer hair cells with selectively ototoxic drugs degrades the ear's responsiveness still more profoundly.

When stimulated electrically, an isolated outer hair cell displays the unique phenomenon of electromotility: The cell body shortens when depolarized and elongates when hyperpolarized (Figure 30–15). This response can occur at frequencies exceeding 80 kHz, an attractive feature for a process postulated to assist high-frequency hearing.

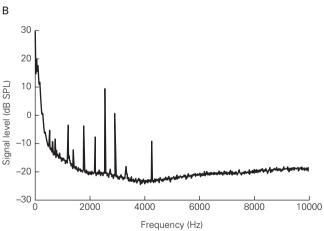

Figure 30-14 The cochlea actively emits sounds.

A. The records display evoked otoacoustic emissions from the ears of five human subjects. A brief click was played into each ear through a miniature speaker. A few milliseconds later a tiny microphone in the external auditory meatus detected one or more bursts of sound emission from the ear. (Reproduced, with permission, from Wilson 1980.)

B. Under suitably quiet recording conditions, spontaneous otoacoustic emissions occur in most normal human ears. This spectrum displays the acoustic power of six prominent emissions and several smaller ones. (Reproduced, with permission, from Murphy et al. 1995.)

The energy for these movements is drawn from the experimentally imposed electrical field rather than from hydrolysis of an energy-rich substrate such as adenosine triphosphate (ATP). Movement occurs when changes in the electric field across the membrane reorient molecules of the protein prestin. The concerted movement of several million of these molecules changes the membrane's area and thus the cell's length. When an outer hair cell transduces mechanical stimulation of its hair bundle into receptor potentials, cochlear amplification might then occur as voltage-induced movement of the cell body augments basilar-membrane motion. Consistent with this hypothesis, mutation of certain amino-acid residues required for

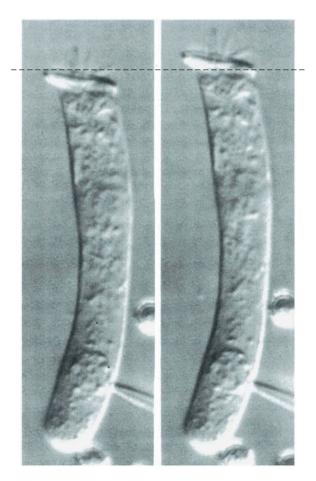

Figure 30–15 Voltage-induced motion of an outer hair cell. Depolarization of an isolated outer hair cell through the electrode at its base causes the cell body to shorten (left); hyperpolarization causes it to lengthen (right). The oscillatory motions of outer hair cells may provide the mechanical energy that amplifies basilar-membrane motion and thus enhances the sensitivity of human hearing. (Reproduced, with permission, from Holley and Ashmore 1988.)

the voltage sensitivity of prestin abolishes the active process in mice.

Because sharp tuning, high sensitivity, and otoacoustic emissions are also observed in animals that lack outer hair cells, electromotility cannot be the only form of mechanical amplification by hair cells. In addition to detecting stimuli, hair bundles are also mechanically active and contribute to amplification. Hair bundles can make spontaneous back-and-forth movements that might underlie spontaneous otoacoustic emissions. Under experimental conditions bundles can exert force against stimulus probes, performing mechanical work and thereby amplifying the input. In vitro experiments indicate that active hair-bundle motility contributes to the cochlear active process even in the mammalian ear.

Several features of auditory responsiveness suggest that cochlear hair cells operate on the verge of an instability termed the Hopf bifurcation. This phenomenon explains hair cells' amplification and frequency selectivity, their nonlinear sensitivity to stimulus intensity, and their capacity to become unstable and spontaneously emit sound. The fact that active hair-bundle motility demonstrates a Hopf bifurcation in vitro provides further evidence that this mechanism contributes to cochlear amplification.

Although active hair-bundle movements have been demonstrated at sound frequencies as high as a few kilohertz, it remains uncertain whether bundles can generate forces at the very high frequencies at which sharp frequency selectivity and otoacoustic emissions are observed in the mammalian cochlea. Active hair-bundle motility and electromotility may function synergistically, with the former serving metaphorically as a tuner and preamplifier and the latter as a power amplifier. Alternatively, hair-bundle motility may operate at relatively low frequencies but be superseded by electromotility at the highest frequencies.

Hair Cells Use Specialized Ribbon Synapses

In addition to being sensory receptors, hair cells also form synapses with sensory neurons. The basolateral membrane of each cell contains several presynaptic active zones at which chemical neurotransmitter is released. An active zone is characterized by four prominent morphological features (Figure 30–16).

A presynaptic dense body or synaptic ribbon lies in the cytoplasm adjacent to the release site. This fibrillar, osmiophilic structure may be spherical, ovoidal,

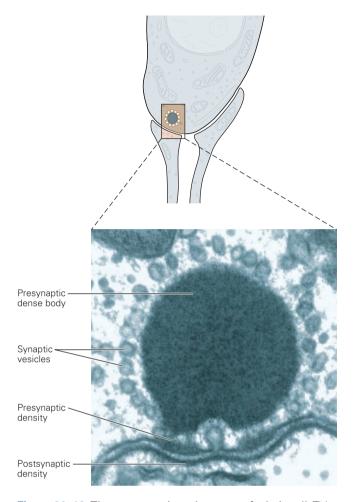

Figure 30–16 The presynaptic active zone of a hair cell. This transmission electron micrograph shows the spherical presynaptic dense body or synaptic ribbon that is characteristic of the hair cell's presynaptic active zone. It is surrounded by clear synaptic vesicles. Beneath the ribbon lies a presynaptic density, in the middle of which one vesicle is undergoing exocytosis. A modest postsynaptic density lies along the inner aspect of the plasmalemma of the afferent terminal. (Reproduced, with permission, from Jacobs and Hudspeth 1990.)

or flattened, and usually measures a few hundred nanometers across. The dense body resembles the synaptic ribbon of a photoreceptor cell and represents a specialized elaboration of the smaller presynaptic densities found at the neuromuscular junction and at central nervous system synapses. In addition to molecular components shared with conventional synapses, ribbon synapses contain large amounts of the protein ribeye.

The presynaptic ribbon is surrounded by clear synaptic vesicles, each 35 nm to 40 nm in diameter, which

are attached to the dense body by tenuous filaments. Between the dense body and the presynaptic plasma membrane lies a striking presynaptic density that comprises several short rows of fuzzy material. Within the plasmalemma rows of large particles are aligned with the strips of presynaptic density. These particles are thought to include the Ca²⁺ channels involved in the release of transmitter as well as the K⁺ channels that participate in electrical resonance.

Studies of nonmammalian experimental models show that, as with most other synapses (see Chapter 12), the release of transmitter by hair cells is evoked by presynaptic depolarization and requires Ca²⁺ from the extracellular medium. Hair cells lack synaptotagmins 1 and 2, however, and the role of those proteins as rapid Ca²⁺ sensors has probably been assumed by the protein otoferlin, which also promotes the replenishment of synaptic vesicles. Postsynaptic recordings indicate that the release of the hair cell's synaptic transmitter is quantal in nature, resembling that of the neuromuscular junction. Although glutamate is the principal afferent neurotransmitter, other substances are released as well.

The presynaptic apparatus of hair cells has several unusual features that underlie the signaling abilities of these cells. Hair cells release synaptic transmitter continuously at rest. The rate of transmitter release can then be modulated upward or downward, depending on whether the hair cell is respectively depolarized or hyperpolarized. Consistent with this observation, the Ca²⁺ channels of hair cells are activated at the resting potential, providing a steady leak of Ca²⁺ that evokes transmitter release from unstimulated cells. Another unusual feature of the hair cell's synapses is that, like those of photoreceptors, they must be able to release neurotransmitter reliably in response to a threshold receptor potential of only 100 µV or so. This feature, too, results from the fact that the presynaptic Ca²⁺ channels are activated at the resting potential.

Most hair cells receive inputs from neurons in the brain stem at large boutons on the basolateral cell surface. These efferent terminals contain numerous clear synaptic vesicles about 50 nm in diameter as well as a smaller number of larger, dense-core vesicles. The principal transmitter at these synapses is acetylcholine (ACh); calcitonin gene–related peptide (CGRP) also occurs in efferent terminals and may be co-released with ACh. ACh binds nicotinic ionotropic receptors consisting of $\alpha 9$ and $\alpha 10$ subunits. These receptor-channels have a substantial permeability to Ca^{2+} as well as Na^+ and K^+ . The Ca^{2+} that enters through these channels activates small-conductance Ca^{2+} -sensitive K^+

channels (SK channels), whose opening leads to a protracted hyperpolarization. The cytoplasm of a hair cell immediately beneath each efferent terminal holds a single cisterna of smooth endoplasmic reticulum. This structure may be involved in the reuptake of the Ca²⁺ that enters in response to efferent stimulation.

The best-understood role of efferent input in the cochlea is its effect on hair cells that employ electrical resonance for frequency tuning. Stimulation of the efferent nerve fibers hyperpolarizes a hair cell. The associated increase in membrane conductance perturbs the critically tuned resonance circuit in the cell's membrane, thus decreasing both the sharpness of frequency selectivity and the gain of electrical amplification. In the mammalian cochlea, where efferent fibers contact outer hair cells, the efferent system desensitizes the cochlea by turning down the active process.

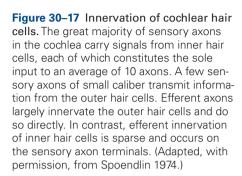

Auditory Information Flows Initially Through the Cochlear Nerve

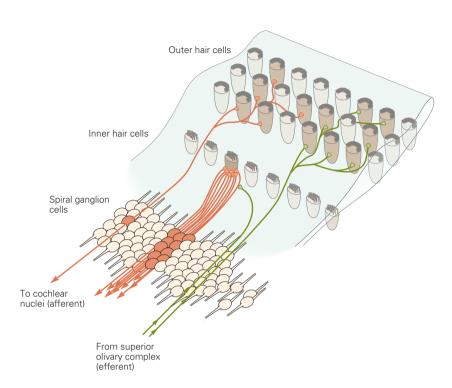

Bipolar Neurons in the Spiral Ganglion Innervate Cochlear Hair Cells

Information flows from cochlear hair cells to primary sensory neurons whose cell bodies lie in the cochlear ganglion. The central processes of these bipolar neurons form the cochlear division of the vestibulocochlear nerve (cranial nerve VIII). Because this ganglion follows a spiral course within the bony core of the cochlea, it is also called the *spiral ganglion*. Approximately 30,000 ganglion cells innervate the hair cells of each inner ear.

The afferent pathways from the human cochlea reflect the functional distinction between inner and outer hair cells. At least 90% of the spiral ganglion cells terminate on inner hair cells (Figure 30–17). Each axon contacts only a single inner hair cell, but each cell directs its output to several nerve fibers, on average nearly 10. This arrangement has three important consequences.

First, the neural information from which hearing arises originates almost entirely at inner hair cells. Second, because the output of each inner hair cell is sampled by many afferent nerve fibers, the information from one receptor is encoded independently in several parallel channels. Third, at any point along the cochlear spiral, or at any position within the spiral ganglion, each ganglion cell responds best to stimulation at the characteristic frequency of the presynaptic hair cell. The tonotopic organization of the auditory

neural pathways thus begins at the earliest possible site, immediately postsynaptic to inner hair cells.

Relatively few cochlear ganglion cells contact outer hair cells, and each such neuron extends branching terminals to numerous outer hair cells. Although the ganglion cells that receive input from outer hair cells are known to project into the central nervous system, these neurons are so few that it is not certain whether their projections contribute significantly to the analysis of sound.

The patterns of efferent and afferent connections of cochlear hair cells are complementary. Mature inner hair cells do not receive efferent input; just beneath these cells, however, are extensive axo-axonic synaptic contacts between efferent axon terminals and the endings of afferent nerve fibers. In contrast, efferent nerves have extensive connections with outer hair cells on their basolateral surfaces. Each outer hair cell receives input from several large efferent terminals, which fill the space between the cell's base and the associated Deiters's cell.

Cochlear Nerve Fibers Encode Stimulus Frequency and Intensity

The acoustic sensitivity of axons in the cochlear nerve mirrors the connection pattern of the spiral ganglion cells. Each axon is most responsive to a characteristic frequency. Stimuli of lower or higher frequency also evoke responses but only when presented at greater intensities. An axon's responsiveness may be characterized by a tuning curve, which is V-shaped like the curves for basilar-membrane motion and hair-cell sensitivity (Figure 30–12). The tuning curves for nerve fibers with different characteristic frequencies resemble one another but are shifted along the abscissa.

The relation between sound-pressure level and firing rate in each fiber of the cochlear nerve is approximately linear. Because of the dependence of level on sound pressure, this relation implies that sound pressure is logarithmically encoded by neuronal activity. Very loud sounds saturate a neuron's response. Because an action potential and the subsequent refractory period last almost 1 ms, the greatest sustainable firing rate is somewhat above 500 spikes per second.

Even among nerve fibers with the same characteristic frequency, the threshold of responsiveness varies from axon to axon. The most sensitive fibers, whose response thresholds extend down to approximately 0 dB, characteristically have high rates of spontaneous activity and produce saturating responses for stimulation at moderate intensities, approximately 40 dB. At the opposite extreme, the least sensitive afferent fibers have less spontaneous activity and much higher thresholds but respond in graded fashion to intensities in excess of 100 dB. The activity patterns of most fibers range between these extremes.

The afferent neurons of lowest sensitivity contact the surface of an inner hair cell nearest the axis of the cochlear spiral. The most sensitive afferent neurons contact the hair cell's opposite side. The multiple innervation of each inner hair cell is therefore not wholly redundant. Instead, the output from a given hair cell is directed into several parallel channels of differing sensitivity and dynamic range.

The firing pattern of fibers in the eighth cranial nerve has both phasic and tonic components. Brisk firing occurs at the onset of a tone presented for a few seconds. As adaptation occurs, however, the firing rate declines to a plateau level over a few tens of milliseconds. When stimulation ceases there is usually a transitory cessation of activity with a similar time course before resumption of the spontaneous firing rate (Figure 30–18).

When a periodic stimulus such as a pure tone is presented, the firing pattern of a cochlear nerve fiber encodes information about the periodicity of the stimulus. For example, a relatively low-frequency tone at a moderate intensity might produce one spike in a nerve fiber during each cycle of stimulation. The phase of firing is also stereotyped. Each action potential might occur, for example, during the compressive phase of the stimulus. As the stimulation frequency rises, the stimuli eventually become so rapid that the nerve fiber can no longer produce action potentials on a cycle-by-cycle basis. Up to a frequency in excess of 4 kHz, however, phase-locking persists; a fiber may produce an action potential only every few cycles of the stimulus, but its firing continues to occur at a particular phase in the stimulus cycle.

Periodicity in neuronal firing enhances the information about the stimulus frequency. Any pure tone of sufficient intensity evokes firing in numerous cochlear nerve fibers. Those fibers whose characteristic frequency coincides with the frequency of the stimulus respond at the lowest stimulus level, but respond still more briskly for stimuli of moderate intensity. Other nerve fibers with characteristic frequencies close to the stimulus also respond, although somewhat less vigorously. Regardless of their characteristic frequencies, however, all the responsive fibers display phase locking: Each tends to fire during a particular part of the stimulus cycle.

The central nervous system can therefore gain information about stimulus frequency in two ways. First, there is a *place code;* the fibers are arrayed in a tonotopic map in which the position is related to characteristic frequency. Second, there is a *frequency code;* the fibers fire at a rate that signals the frequency of the stimulus. Frequency coding is of particular importance

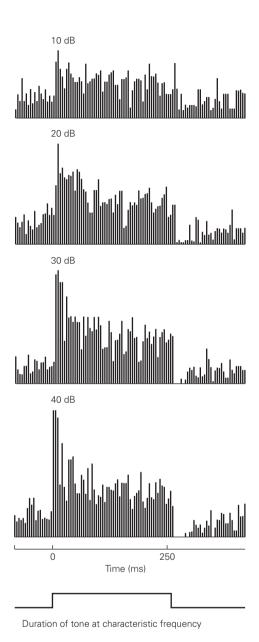

Figure 30–18 The firing pattern of a cochlear nerve fiber. A cochlear nerve fiber is stimulated for somewhat more than 250 ms with a tone burst at about 5 kHz, the cell's characteristic frequency. After a quiet period the stimulus is repeated. Histograms show the average response patterns of the fiber as a function of stimulus intensity. The sample period is divided into discrete temporal bins, and the number of spikes occurring in each bin is displayed. An initial, phasic increase in firing is correlated with the onset of the stimulus. The discharge continues during the remainder of the stimulus following adaptation, but decreases following termination. This pattern is evident when the stimulus is 20 dB or more above threshold. Activity gradually returns to baseline during the interval between stimuli. (Adapted, with permission, from Kiang 1965.)

when a sound is loud enough to saturate the neuronal firing rate. Although fibers with different characteristic frequencies respond to such a stimulus, each provides information about the stimulus frequency in its firing pattern.

Sensorineural Hearing Loss Is Common but Treatable

Whether mild or profound, most deafness falls into the category of *sensorineural hearing loss*, often misnamed "nerve deafness." Although hearing loss can result from damage to the eighth cranial nerve, for example from an acoustic neuroma (see Chapter 45), deafness stems primarily from the loss of cochlear hair cells.

The 16,000 hair cells in each human cochlea are not replaced by cell division but must last a lifetime. However, in amphibians and birds supporting cells can be experimentally induced to divide and their progeny to produce new hair cells. In the zebrafish some hair cell populations are regenerated continually by the activity of stem cells. Researchers have recently succeeded in replenishing mammalian hair cells in vitro. Until we understand how hair cells can be restored to the organ of Corti, however, we must cope with hearing loss, which is becoming more prevalent because of our aging population and increasingly noisy environment.

The last few decades have brought remarkable advances in our ability to treat deafness. For the majority of patients who have significant residual hearing, hearing aids can amplify sounds to a level sufficient to activate the surviving hair cells. A modern aid is custom-tailored to compensate for each individual's hearing loss, so that the device most amplifies sounds at frequencies to which the wearer is least sensitive while providing little or no enhancement to those that can still be heard well. To the credit of our society, the stigma formerly associated with wearing a hearing aid is dissipating rapidly; using such an aid is now regarded as unremarkable as wearing eyeglasses.

When most or all of a person's cochlear hair cells have degenerated, no amount of amplification can assist hearing. However, hearing can be restored by bypassing the damaged cochlea with a cochlear prosthesis. A user wears a compact unit that picks up sounds, decomposes them into their frequency components, and forwards electronic signals representing these constituents along separate wires to small antennas situated just behind the auricle. The signals are then transmitted transdermally to receiving antennas implanted in the temporal bone. From there, fine wires

bear the signals to appropriate electrodes implanted at various positions along the scala tympani. Activation of the electrodes excites action potentials in nearby axons (Figure 30–19).

The cochlear prosthesis takes advantage of the tonotopic representation of stimulus frequency along the cochlea. Because the axons innervating each segment of the cochlea are concerned with a specific, narrow range of frequencies, each electrode in a prosthesis can excite a cluster of nerve fibers that are sensitive to similar frequencies. The stimulated neurons then forward their outputs along the intact eighth nerve to the central nervous system, where these signals are interpreted as a sound of the frequency represented at that position on the basilar membrane. An array of approximately 20 electrodes can mimic a complex sound by appropriately stimulating several clusters of neurons.

Cochlear prostheses have now been implanted in more than 100,000 patients worldwide. Their effectiveness varies widely from person to person. In the best outcome an individual can understand speech nearly as well as a normally hearing person and can even conduct telephone conversations. At the other extreme are patients who derive little benefit from prostheses, presumably because of extensive degeneration of the nerve fibers near the electrode array. Most patients find their prostheses of great value. Even if hearing is not completely restored, the devices help in lip reading and alert patients to noises in the environment.

The other way to overcome deafness relies not on high technology but on the efforts of generations of deaf individuals and their teachers. Sign languages have probably existed for as long as humans have spoken, and perhaps even longer. Many such languages represent attempts to translate spoken language into a system of hand signs. Signed English, for example, provides an effective means of communication that largely obeys the rules of English speech.

However, sign languages that diverge more radically from spoken languages are far more effective. Freed from the constraint of mirroring English, American Sign Language, or ASL, has become an elegant and eloquent language in its own right. Linguists now recognize American Sign Language as a distinct language whose range of expressiveness generally matches—and sometimes exceeds—that of spoken English.

An Overall View

Hearing, a key sense in human communication, begins with capture of sound by the ear. Mechanical energy captured by the outer ear flows through the middle

A Sound transmission to cochlea

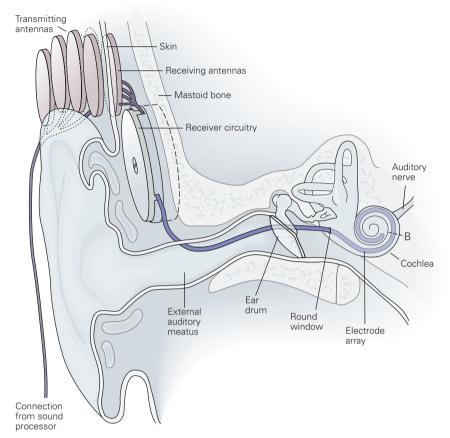

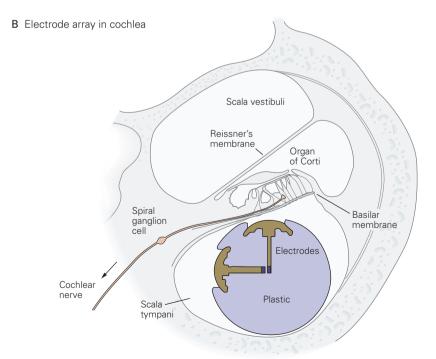

Figure 30–19 A cochlear prosthesis. (Reproduced, with permission, from Loeb et al. 1983.)

A. Transmitting antennas receive electrical signals from a sound processor, located behind the subject's auricle or on the frame of his eyeglasses, and forward them across the skin to receiving antennas implanted subdermally behind the auricle. The signals are then conveyed in a fine cable to an electrode array in the cochlea.

B. This cross section of the cochlea shows the placement of pairs of electrodes in the scala tympani. A portion of the extracellular current passed between an electrode pair is intercepted by nearby cochlear nerve fibers, which are thus excited and send action potentials to the brain.

ear to the cochlea, where it causes the elastic basilar membrane to oscillate. Aligned along the basilar membrane in a tonotopic array, 16,000 hair cells detect the frequency components of a stimulus and transduce them into receptor potentials that cause sensory neurons to fire.

As the population ages and as society becomes more concerned about hearing loss, physicians will increasingly confront patients and families who are experiencing the social difficulties associated with deafness. This subject is at present politically charged. On the one hand, the rapid technical improvement in cochlear prostheses leads their developers to advocate use of the devices whenever practical, including for young children. Many members of the deaf community, on the other hand, believe that widespread implantation of cochlear prostheses, particularly in children, will foster a generation of individuals whose ability to communicate is dependent on technological support of as yet unproved durability. The extensive use of prostheses might also diminish the use of American Sign Language and thus reverse the deaf community's remarkable recent advances.

Although this debate will not soon subside, it is worthwhile to emphasize the most positive aspect of the issue. A few decades ago there were no widely effective ways of coping with profound deafness; now there are two. Moreover, these solutions are not mutually exclusive; with a cochlear prosthesis a deaf individual can benefit from bilingualism in spoken English and American Sign Language.

An Overall View

Because of its role in the understanding and production of speech, auditory perception is one of the most important sensory modalities in humans. In most animals hearing is crucial for localizing and identifying sounds; for some species, hearing additionally guides the learning of vocal behavior.

Once sounds have been transformed into electrical responses in the cochlea, a rich hierarchy of auditory circuits analyzes and processes these signals to give rise to auditory perception. The auditory system differs from most other sensory systems in that the location of stimuli in space is not conveyed by the spatial arrangement of the afferent pathways. Instead, the localization and identification of sounds is constructed from patterns

of frequencies mapped at the two ears as well as from their relative intensity and timing. The auditory system is also notable for its temporal sensitivity; time differences as small as $10~\mu s$ can be detected. Auditory pathways resemble other sensory systems, however, in that different features of acoustic information are processed in discrete circuits that eventually converge to form complex representations of sound.

In addition to studies of primates and mammals such as cats and rodents, research on animals with especially acute or specialized auditory capacities—frogs, bats, barn owls, and songbirds—has provided a wealth of information about auditory processing. Many of the principles learned from the study of such auditory specialists have proven to be generally applicable. They are simply easier to detect in animals with specialized mechanisms.

Multiple Types of Information Are Present in Sounds

Hearing helps to alert animals to the presence of unseen dangers or opportunities, and in many species also serves as a basis for communication. Information about where sounds arise and what they mean must be extracted from the representations of the physical characteristics of sound at each of the ears. To understand how animals process sound, it is useful first to consider what cues are available.

Most vertebrates take advantage of having two ears for localizing sounds in the horizontal plane. Sound sources at different positions in that plane affect the two ears differentially: Sound arrives earlier and is more intense at the ear nearer the source (Figure 31–1A). The size of the head determines how interaural time delays are related to the location of sound sources; the neuronal circuitry determines the precision with which time delays are resolved. Because sound travels at roughly 340 m/s in air, the maximal interaural delay in humans is approximately 600 µs; in small birds the greatest delay is only 35 µs. Humans can resolve the location of a sound source directly ahead to within approximately 1 degree, corresponding to an interaural time difference of 10 µs. Interaural time differences are particularly well conveyed by neurons that encode relatively low frequencies, for groups of these neurons can fire at the same position in every cycle of the sound and in this way encode the interaural time difference as an interaural phase difference.

Sounds of high frequencies produce *sound shadows* or intensity differences between the two ears. For many mammals with small heads, high-frequency

sounds provide the primary cue for localizing sound in the horizontal plane.

Spectral filtering in mammals allows sounds to be localized in the vertical plane and with a single ear (Figure 31–1B). High-frequency sounds, with wavelengths that are close to or smaller than the dimensions of the head, shoulders, and external ears, interact with those parts of the body to produce constructive and destructive interference, introducing broad spectral peaks and narrow, deep spectral notches whose frequency changes with the location of the sound. Highfrequency sounds from different origins are filtered differently because in mammals the shape of the external ear differs back-to-front as well as top-to-bottom. Animals learn to use these spectral cues to locate sound sources. If the shape of the ear is experimentally altered, even adult humans can learn to make use of a new pattern of spectral cues. If animals lose hearing in one ear, they lose interaural timing and intensity cues and must depend completely on spectral cues for localizing sounds.

How do we make sense of the sounds that we hear? Most natural sounds contain energy over a wide range of frequencies and change rapidly over time. The information used to recognize sounds varies among animal species, and depends on listening conditions and experience. Human speech, for example, can be understood in the midst of noise, over electronic devices that distort sounds, and even through cochlear implants. One reason for its robustness is that speech contains redundant cues: The vocal apparatus produces sounds in which multiple parameters covary. At the same time, this makes the task of understanding how animals recognize patterns a complicated one. It is not clear which cues are used by animals under what conditions.

Music is a source of pleasure to human beings. Musical instruments and human voices produce sounds that have energy at the fundamental frequency that corresponds to the perceived pitch as well as at multiples of that frequency that give sounds a quality that allows us, for example, to distinguish a flute from a violin when their pitch is the same. Musical pitches are largely in the low frequency range in which auditory nerve fibers fire in phase with sounds. Musical sounds when combined simultaneously produce chords, and chord progressions produce melodies. Euphonious, pleasant chords elicit regular, periodic firing in the auditory nerve in which the most common interval between action potentials corresponds to the period of the perceived pitch. In dissonant sounds there is less regularity both in the sound itself and in the firing of auditory nerve fibers; the component frequencies are so close that they interfere with one another instead of periodically reinforcing one another.

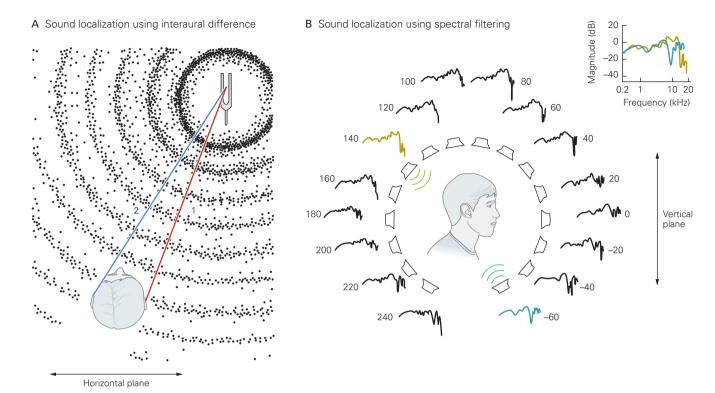

Figure 31-1 Cues for localizing sound sources.

A. A sound arising in the horizontal plane arrives differently at the two ears. Sounds arrive earlier and are louder at the ear nearer the source. Interaural time and intensity differences are cues for localizing sound sources in the horizontal plane, or azimuth. A sound that arises directly in the front or back travels the same distance to the right and left ears and thus arrives at both ears simultaneously. A sound that arises from the side travels a shorter distance to the near ear than to the far ear and thus arrives at the near ear before it arrives at the far ear. In humans the maximal interaural time difference is approximately 600 µs. High-frequency sounds, with short wavelengths, are deflected by the head, producing a sound shadow on the far side. Interaural intensity differences are used by mammals as an additional cue for localizing sounds in the horizontal plane. Interaural time and intensity do not vary with the movement of sound sources in the vertical plane, so it is impossible to localize a pure sinusoidal tone in the vertical plane. (Adapted, with permission, from Geisler 1998.)

B. Mammals can localize broadband sounds in both the vertical and horizontal planes on the basis of spectral filtering. When a noise that has equal energy at all frequencies over the human hearing range (*white noise*) is presented through a speaker, the ear, head, and shoulders cancel energy at some frequencies and enhance

others. The amount of sound energy at each frequency at the ear canal is shown by the traces beside each speaker, which plot in decibels the power spectrum of sound that reaches the eardrum relative to the white noise that is produced by the speakers. For a white noise the power spectrum is flat. Note that by the time the noise has reached the bottom of the ear canal its spectrum is no longer flat. The small plot in the upper right compares spectral filtering of sounds coming from low in the front (blue) with sounds coming from behind and above the listener's head (brown). At high frequencies filtering by the ear introduces deep notches into spectra that vary depending on where the sounds arose. Sounds that lack energy at high frequencies and narrowband sounds are difficult to localize in the vertical plane. Spectral filtering also varies in the horizontal plane and provides the only location cue to animals that have lost hearing in one ear. You can test the salience of these spectral cues with a simple experiment. Close your eyes as a friend jingles keys directly in front of you at various elevations. Compare your ability to localize sounds under normal conditions and when you distort the shape of both ears by pushing them with your fingers from the back. The numerical values of the sound waves are measured in degrees beginning in front of the listener (-60 degrees) and moving in 20-degree increments in a vertical arc until the sound is broadcast behind the listener at 240 degrees. (Data reproduced, with permission, from D. Kistler and F. Wightman.)

The Neural Representation of Sound Begins in the Cochlear Nuclei

The neural pathways that process acoustic information extend from the ear to the brain stem, through the midbrain and thalamus, to the cerebral cortex (Figure 31–2). Acoustic information is conveyed from the cochlea by the central processes of cochlear ganglion cells (see Figure 30–17) that terminate in the cochlear nuclei in the brain stem. There information is relayed to several different types of neurons, most of which are arrayed tonotopically.

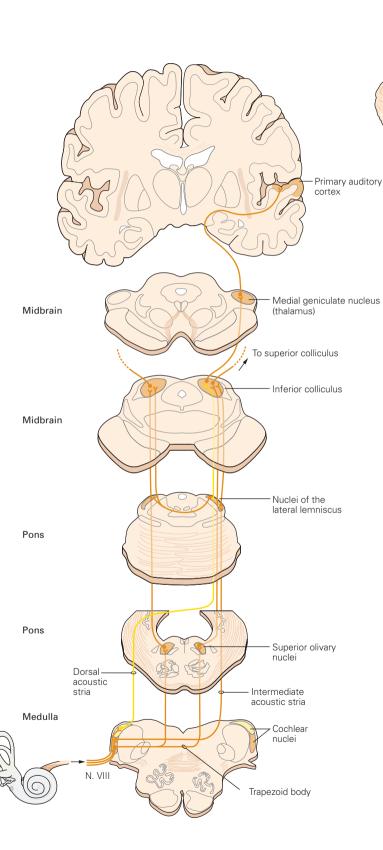

Figure 31–2 The central auditory pathways extend from the brain stem through the midbrain and thalamus to the auditory cortex. All cochlear (eighth cranial) nerve fibers terminate in the cochlear nuclei of the brain stem. The neurons of these nuclei project in several parallel pathways to the inferior colliculus. Their axons exit through the trapezoid body, intermediate acoustic stria, or dorsal acoustic stria. Some cells terminate directly in the inferior colliculus. Others contact cells in the superior olivary complex and in the nuclei of the lateral lemniscus, which in turn project to the inferior colliculus. Neurons of the inferior colliculus project to the superior colliculus and to the medial geniculate nucleus of the thalamus. Thalamic neurons project to the auditory cortex. Only the cochlear nuclei and the ventral nuclei of the lateral lemniscus receive monaural input. (Adapted, with permission, from Brodal 1981.)

The axons of each of these types of neurons take a different route and terminate on separate targets in the brain stem and midbrain, ultimately bringing acoustic information mainly to the contralateral inferior colliculus. Some of the pathways from the cochlear nuclei to the inferior colliculus are direct; others involve one or two synaptic stages in brain stem auditory nuclei. From the inferior colliculi acoustic information flows two ways: to the ipsilateral superior colliculus, where it participates in orienting the head and eyes in response to sounds, and to the ipsilateral thalamus, the relay to auditory areas of the cerebral cortex. The afferent auditory pathways from the periphery to higher brain regions include efferent feedback at many levels.

The Cochlear Nerve Imposes a Tonotopic Organization on the Cochlear Nuclei and Distributes Acoustic Information into Parallel Pathways

The afferent nerve fibers from cochlear ganglion cells are bundled in the cochlear or auditory component of the vestibulocochlear (eighth cranial) nerve and terminate exclusively in the cochlear nuclei. The cochlear nerve in mammals contains two groups of fibers: a large contingent (95%) of myelinated fibers that receives input from inner hair cells, and a small number (5%) of unmyelinated fibers that receives input from outer hair cells.

The larger, more numerous, myelinated fibers are much better understood than the unmyelinated fibers. Each myelinated fiber detects energy over a narrow range of frequencies; together these fibers carry information about the moment-to-monent variation in the frequency content of sounds. The unmyelinated fibers terminate on the large neurons in the ventral cochlear nuclei and on the small granule cells that surround the ventral cochlear nuclei. These fibers integrate information from a relatively wide region of the cochlea and are therefore unlikely to be as sharply tuned as the myelinated fibers. Because it is difficult to record from these tiny fibers, the information they convey to the brain is unknown. Indirect evidence suggests that they encode the intensity of sounds over a wide dynamic range.

Two features of the cochlear nuclei are important. First, the cochlear nerve fibers terminate in these nuclei in a tonotopic organization. Fibers that carry information from the apical end of the cochlea, which detects low frequencies, terminate ventrally in the ventral and dorsal cochlear nuclei; those that carry information from the basal end of the cochlea, which detects high frequencies, terminate dorsally (Figure 31–3). Second, each cochlear nerve fiber innervates several different

areas within the cochlear nuclei, contacting various types of neurons that have distinct projection patterns to higher auditory centers. As a result, the auditory pathway is split into at least four parallel ascending pathways that simultaneously extract different facets of acoustic information from the representation of sound carried by cochlear nerve fibers.

The Ventral Cochlear Nucleus Extracts Information About the Temporal and Spectral Structure of Sounds

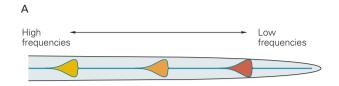

The principal cells of the unlayered ventral cochlear nucleus sharpen timing and spectral information and convey it to other auditory nuclei in the brain stem. Three types of neurons are intermingled and form separate pathways through the brain stem.

Bushy cells project bilaterally to the superior olivary complex. This pathway has two parts, one through the medial superior olive and the other through the lateral superior olive and medial nucleus of the trapezoid body. Large spherical bushy cells sense low frequencies and project bilaterally to the medial superior olive, forming a circuit that detects interaural time delay and permits the localization of low-frequency sounds in the horizontal plane. Small spherical bushy cells and globular bushy cells sense high frequencies and are associated with the lateral superior olive. Small spherical bushy cells probably excite the lateral superior olive ipsilaterally. The globular bushy cells, through calyceal axonal endings that surround the postsynaptic neurons, excite neurons in the contralateral medial nucleus of the trapezoid body that in turn inhibit principal cells of the lateral superior olive. The pathways through the lateral superior olive are involved in the detection of interaural intensity differences and contribute to the localization of high-frequency sounds in the horizontal plane.

Stellate cells excite neurons in the ipsilateral dorsal cochlear nucleus, probably in the ipsilateral lateral superior olive, in the periolivary nuclei, and in the contralateral ventral nucleus of the lateral lemniscus through collaterals of axons that project to the contralateral inferior colliculus. The tonotopic array of stellate cells encodes the spectra of sounds.

Octopus cells excite targets in the contralateral periolivary region and the ventral nucleus of the lateral lemniscus. These neurons detect onset transients and periodicity in sounds and may be involved in the recognition of sound patterns.

The differences in the integrative tasks performed by these pathways are evident in the synaptic structures and shapes of the three types of neurons.

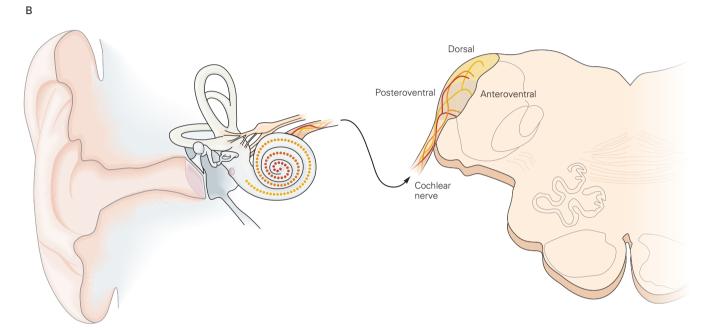

Figure 31–3 Cochlear nerve fibers terminate in the dorsal and ventral cochlear nuclei in a tonotopic organization.

A. Stimulation with three frequencies of sound causes the basilar membrane (uncoiled for illustration) to vibrate at three positions, exciting distinct populations of hair cells and their afferent nerve fibers.

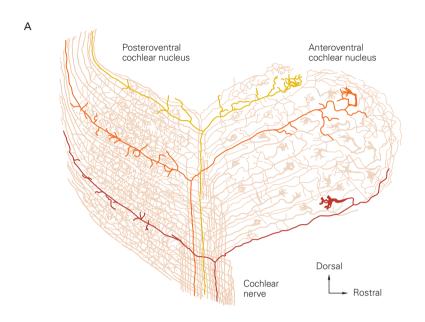

B. Cochlear nerve fibers project in a tonotopic pattern to the cochlear nuclei. Those encoding the lowest frequencies terminate most ventrally, whereas those encoding higher frequencies

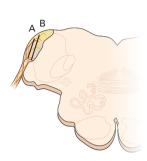

terminate more dorsally. The cochlear nuclei include the unlayered ventral cochlear nucleus and the layered dorsal cochlear nucleus. Each afferent fiber enters at the nerve root and splits into branches that run anteriorly (the ascending branch) and posteriorly (the descending branch). The ventral cochlear nucleus is thus divided functionally into anteroventral and posteroventral divisions. The orderly termination of cochlear nerve fibers imposes a tonotopic map on each subdivision of the ventral cochlear nucleus and on the dorsal cochlear nucleus.

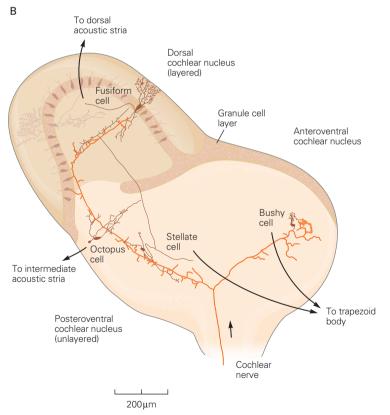

The shapes of their dendrites differ, reflecting differences in the way they collect information from cochlear nerve fibers (Figure 31–4A,B). The dendrites of bushy and stellate cells span only a small range of the tonotopic array of auditory nerve fibers, receive input from relatively few auditory nerve fibers, and are consequently sharply tuned. Many of the inputs to bushy cells are from unusually large terminals that surround the cell bodies, meeting the need for large synaptic currents. Octopus cells, in contrast, have dendrites that span a large proportion of the array of afferent fibers, receiving input from many cochlear nerve fibers, and

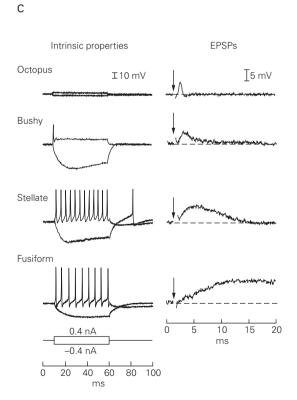

thus are broadly tuned. Their need for large synaptic currents is met by summing inputs from large numbers of small terminals.

The biophysical properties of neurons determine how synaptic currents are converted to voltage changes and over how long a time synaptic inputs are integrated. Octopus and bushy cells in the ventral cochlear nucleus are able to respond with exceptionally rapid and precisely timed synaptic potentials. These neurons have a prominent, low-voltage-activated K⁺ conductance that confers a low input resistance and rapid responsiveness and prevents repetitive firing (Figure

31–4C). The large synaptic currents that are required to trigger action potentials in these leaky cells are delivered through rapidly gated, high-conductance, AMPA-type (α -amino-3-hydroxy-5-methylisoxazole-4-propionate) glutamate receptors found at many synaptic release sites. In contrast, stellate cells, in which even relatively small depolarizing currents produce large, protracted voltage changes, generate slower excitatory postsynaptic potentials (EPSPs) in response to synaptic currents. NMDA-type (N-methyl-p-aspartate) glutamate receptors enhance the slow responses.

Neurons in the ventral cochlear nucleus are able to encode different features of sounds because of differences in the pattern of input and their biophysical properties. Octopus cells detect synchronous firing in cochlear nerve fibers with exceptional temporal precision. Large, low-voltage-activated K⁺ and hyperpolarization-activated conductances give octopus cells exceptionally low input resistances so that individual cochlear nerve fibers can produce synaptic responses of only approximately 1 mV and only 1 ms in duration. To fire action potentials octopus cells require summation of the rising phases of numerous synaptic inputs. Individual octopus cells detect coincident firing in the relatively large number of cochlear nerve fibers (more than 60) that contact them. Coincident firing in large numbers of cochlear nerve fibers is produced by periodic sounds such as vowels and musical sounds and by the onset of broadband sounds found in consonants or clicks.

Compared to octopus cells, bushy cells convey a more sharply tuned but less temporally precise version of the firing patterns of cochlear nerve fibers. The roughly 10 cochlear nerve fibers that terminate on each bushy cell deliver relatively large synaptic currents that require summation of only a few inputs to trigger an action potential. Two properties of bushy cells enable these neurons to encode with precision the detailed temporal structure of sounds. The cells' low input resistance shortens the voltage changes produced by the incoming synaptic currents; their need to summate several inputs removes variability in the timing of firing in cochlear nerve fibers by averaging.

The temporal fine structure of sounds that bushy cells encode provides information about the relative time of arrival of inputs to the two ears and is used at the next synaptic stage to form a map of the interaural time differences that underlie the ability to localize sound sources in the horizontal plane. The detection of musical pitch also requires the encoding of the temporal fine structure of sounds, but whether that information is carried through octopus or bushy cells or through a combination of pathways is not known.

Individual stellate cells detect intensity over a narrow frequency range and as a population they provide a continuous representation of the spectrum of sound energy. They are sharply tuned, being driven by only approximately 10 cochlear nerve fibers. Feedforward excitation through other, similarly tuned stellate cells and enhancement of inputs through NMDA-type receptors compensates for adaptation and obscures the fine structure of sound, encoded by cochlear nerve inputs, but allows the tonic firing rate of the cells to reflect the intensity of sounds to which they are tuned. Sideband inhibition enhances the cells' encoding of spectral peaks and troughs. Stellate cells track

Figure 31–4 (Opposite) Cells in the cochlear nuclei extract acoustic information from the distinct electrophysiological properties of individual cochlear nerve fibers.

A. The terminals along the length of each cochlear nerve fiber in the ventral cochlear nucleus differ in size and shape, reflecting differences in their targets. Large end bulbs form synapses on bushy cells; smaller boutons contact stellate and octopus cells. The nerve fibers are color-coded as in Figure 30–3: The yellow fiber encodes the highest frequencies and the red fiber the lowest. (Adapted, with permission, from Cajal 1909.)

B. A layer of granule cells separates the unlayered ventral cochlear nucleus (beige) from the layered dorsal nucleus (brown). In the dorsal cochlear nucleus the cell bodies of fusiform and granule cells are intermingled in a region between the outermost molecular layer and the deep layer. Cochlear nerve fibers, color-coded for frequency as in part A, terminate in both nuclei but with different patterns of convergence on the principal cells. Bushy, stellate, and fusiform cells each receive input from a few auditory nerve fibers and are sharply tuned, whereas

individual octopus cells are contacted by many auditory nerve fibers and are broadly tuned.

C. Differences in the intrinsic electrical properties of the principal cells of the cochlear nuclei are reflected in the patterns of voltage change in the cells. When steadily depolarized, stellate and fusiform cells fire repetitive action potentials, whereas low-voltage-activated conductances prevent repetitive firing in bushy and octopus cells. The low input resistance of bushy and octopus cells in the depolarizing voltage range makes voltage changes rapid but also small; the rise and fall of voltage changes in stellate and fusiform cells is slower. Synaptic currents, too, produce different synaptic potentials. The synaptic potentials are brief in octopus and bushy cells but longer-lasting in stellate and fusiform cells. The brief synaptic responses in bushy and octopus cells require larger synaptic currents but encode the timing of auditory nerve inputs more faithfully than do the longer-lasting responses of stellate or fusiform cells. modulations in intensity on a timescale of tens of milliseconds that is known to be important for understanding speech.

The Dorsal Cochlear Nucleus Integrates Acoustic with Somatosensory Information in Making Use of Spectral Cues for Localizing Sounds

In mammals cochlear nerve fibers extend into a layered dorsal cochlear nucleus (Figure 31–4A,B). The dorsal cochlear nucleus receives input from two systems of neurons that project to different layers.

The outermost molecular layer is the terminus of a system of parallel fibers, the unmyelinated axons of granule cells that are scattered in and around the cochlear nuclei. The parallel fibers terminate on interneurons that bear a strong resemblance to those in the cerebellum. This system transmits somatosensory, vestibular, and auditory information from widespread regions of the brain to the molecular layer.

The deep layer is the terminus of cochlear nerve fibers, which convey acoustic information directly and indirectly through stellate cells of the ventral cochlear nucleus. The cochlear nerve inputs are tonotopically organized in isofrequency laminae that run at right angles to parallel fibers.

Inputs from both systems of fibers are combined in the principal neurons of the dorsal cochlear nucleus, the fusiform cells. Parallel fibers excite fusiform cells on their spiny apical dendrites in the molecular layer at plastic synapses, whereas cochlear nerve fibers and stellate cells of the ventral cochlear nucleus excite fusiform cells on their smooth basal dendrites in the deep layer at synapses that show little plasticity. Both fiber systems also inhibit fusiform cells through inhibitory interneurons.

Eric Young and his colleagues proposed that the dorsal cochlear nucleus helps mammals interpret spectral cues for localization of sound sources. When animals move their head or ears or walk, they affect the angle of incidence of sounds to the ears even when a sound source stays in one place. To make full use of spectral cues, animals must differentiate the predictable cues that are produced by their own movements from the more interesting, unpredictable ones that inform them about the location of external sound sources. The somatosensory and vestibular information about the position of the head and ears, as well as descending information from higher levels of the nervous system about the animal's own movements, can serve to identify the predictable cues. Fusiform cells thus relate the spectral cues they receive through the deep layer with predictable cues received through the molecular layer.

Among vertebrates only mammals have dorsal cochlear nuclei and only mammals have been shown to make use of spectral cues. Most birds and other reptiles hear to only 5 kHz, which corresponds to a wavelength of 6.8 cm. Sounds with wavelengths that exceed 7 cm do not interact with heads whose diameters are less than 2 cm wide and thus do not provide spectral cues. Conversely, humans hear to 20 kHz, corresponding to a wavelength of 1.7 cm; cats and dogs hear to approximately 50 kHz; and mice and bats hear to 100 kHz. The wavelengths of these high-frequency sounds are small with respect to the dimensions of the heads and ears and therefore provide useful spectral cues.

The Superior Olivary Complex of Mammals Contains Separate Circuits for Detecting Interaural Time and Intensity Differences

In many vertebrates, including mammals and birds, neurons in the superior olivary complex compare the activity of cells in the bilateral cochlear nuclei to locate sound sources. Separate circuits detect interaural time and intensity differences.

The Medial Superior Olive Generates a Map of Interaural Time Differences

Differences in arrival times at the ears are not represented at the cochlea. Instead, a map of interaural phase is created in the medial superior olive by a comparison of the timing of firing in responses to sounds from the two ears. Sounds arrive at the near ear before they arrive at the far ear, with interaural time differences being directly related to the location of sound sources in the horizontal plane.

Cochlear nerve fibers tuned to frequencies below 4 kHz and their bushy cell targets encode sounds by firing in phase with the pressure waves. This property is known as *phase-locking*. Although individual neurons may fail to fire at some cycles, the population of neurons represents the fine structure of sound waves by firing with every cycle. In so doing, these neurons carry information about the timing of inputs with every cycle of the sound. Sounds arriving from the side evoke phase-locked firing that is consistently earlier at the near ear than at the far ear, resulting in consistent interaural phase differences (Figure 31–5A).

In 1948 Lloyd Jeffress suggested that an array of detectors of coincident inputs from the two ears, transmitted through *delay lines* comprising axons with systematically differing lengths, could form a map of interaural time differences and thus a map of the

location of sound sources (Figure 31–5B). In such a circuit conduction delays compensate for the early arrival at the near ear. Interaural time delays increase systematically as sounds move from the midline to the side, resulting in coincident firing further toward the edge of the neuronal array.

Such neuronal arrays have indeed been found in the barn owl in the homolog of the medial superior olivary nucleus. Mammals and chickens use a variant of this neuronal arrangement. The principal neurons of the medial superior olive form a sheet of one or a few cells' thickness on each side of the midline. Each neuron has two tufts of dendrites, one extending to the lateral face of the sheet, the other projecting to the medial face of the sheet (Figure 31–5C). The dendrites at the lateral face are contacted by large spherical bushy cells from the ipsilateral cochlear nucleus, whereas the dendrites at the medial face are contacted by large spherical bushy cells of matching best frequency from the contralateral cochlear nucleus. The axons of bushy cells terminate in the contralateral medial superior olive with delay lines just as Jeffress had suggested, but the branches that innervate the ipsilateral medial superior olive are of equal length (see Figure 31–5C).

Each medial superior olive receives coincident inputs from the two ears only when sounds come from the contralateral half of space. As sound sources move from the midline to the most lateral point on the contralateral side of the head, the earlier arrival of sounds at the contralateral ear needs to be compensated by successively longer delay lines. This results in inputs from the two ears coinciding at increasingly posterior regions of the medial superior olive, thereby forming a map of interaural phase. Recent findings indicate that inhibition that is superimposed on these excitatory inputs plays a significant role in sharpening the map of interaural phase.

In responding to interaural phase, individual neurons in the medial superior olive provide ambiguous information about interaural time differences. Phase ambiguities are resolved when sounds have energy at multiple frequencies, as natural sounds almost always do. The sheet of neurons of the medial superior olive forms a representation of interaural phase along the rostrocaudal dimension but its tonotopic innervation by bushy cells imposes a tonotopic organization in the dorsoventral dimension. Sounds that contain energy at multiple frequencies evoke maximal coincident firing in a single dorsoventral column of neurons that localizes sound sources unambiguously.

Each medial superior olive thus forms a map of the location of sound sources in the contralateral hemifield. The striking difference between this spatial map and

those in other sensory systems is that this map is not the result of the spatial arrangement of inputs, like retinotopic or somatosensory maps, but is inferred by the brain from computations made in the afferent pathways.

The Lateral Superior Olive Detects Interaural Intensity Differences

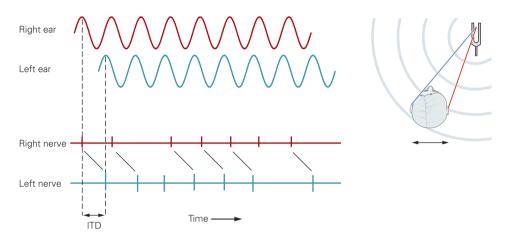

Sounds with wavelengths that are similar to or smaller than the head are deflected by the head, causing the intensity at the near ear to be greater than that at the far ear. In humans interaural intensities can differ in sounds that have frequencies greater than about 2 kHz. Interaural intensity differences produced by such head shadowing are detected by a neuronal circuit that includes the medial nucleus of the trapezoid body and the lateral superior olive.

Although the lateral superior olive does not form a map of the location of sounds in the horizontal plane, it performs the first of several integrative steps that use interaural intensity differences to localize sounds. Neurons in this nucleus balance excitatory input from small spherical bushy cells and stellate cells in the ipsilateral ventral cochlear nucleus with inhibitory input from a disynaptic pathway that includes globular bushy cells in the contralateral ventral cochlear nucleus and principal neurons of the ipsilateral medial nucleus of the trapezoid body (Figure 31-6). Sounds that arise ipsilaterally generate relatively strong excitation and relatively weak inhibition whereas those that arise contralaterally generate stronger inhibition than excitation. Differences in the location of the sound sources that generate differences in the balance between excitation and inhibition are reflected in the firing rates of neurons in the lateral superior olive. Neurons in the lateral superior olive are thus activated more strongly by sounds from the ipsilateral than from the contralateral hemifield.

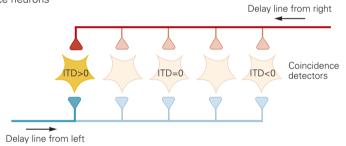

The relative strength of inhibitory and excitatory inputs varies in the population of cells in the lateral superior olive, and thus in the degree of interaural level difference that causes them to stop firing. Although no individual neuron is sharply tuned to a particular interaural intensity difference, the combination of firing from a variety of neurons with different cutoffs conveys the necessary information through a population code.

In order to balance excitation and inhibition stimulated by the same sound, the ipsilateral excitation and contralateral inhibition must arrive at neurons in the lateral superior olive at the same time. Thus excitation that arises monosynaptically from the ipsilateral ventral cochlear nucleus must arrive at the same time as inhibition that arises disynaptically from the contralateral cochlear nucleus. It is probably for this reason that the

C Bilateral medial superior olivary nuclei

axons of globular bushy cells are exceptionally large; their synapses with the principal cells of the medial nucleus of the trapezoid body are the large calyces of Held that produce synaptic responses with short and consistently timed delays. The axons of small spherical bushy cells and cochlear nuclear stellate cells that carry ipsilateral excitation are smaller than those of globular bushy cells and thus conduct more slowly.

The terminals of the globular bushy cells, the calyces of Held, engulf the cell bodies of trapezoid-body neurons so dramatically that they caught the attention of early anatomists and modern biophysicists. A single somatic terminal releases neurotransmitter at numerous release sites and generates large synaptic currents. The capability of making reliable recordings pre- and postsynaptically has allowed the mechanisms of synaptic transmission to be studied in detail at this synapse (see Chapter 12).

Efferent Signals from the Superior Olivary Complex Provide Feedback to the Cochlea

Although sensory systems are largely afferent, bringing sensory information to the brain, recent studies have led to an appreciation of the importance of efferent regulation at many levels of the auditory system, including even efferent signaling to the cochlea from the superior olivary complex in the brain stem.

Figure 31–5 (Opposite) Interaural time differences localize sound sources in the horizontal plane.

A. When a sound, such as a pure tone, arises from the right, the right ear detects the sound earlier than the left ear. The difference in the time of arrival at the two ears is the interaural time delay (ITD). Cochlear nerve fibers and their bushy cell targets fire in phase with changes in sound pressure. Although individual neurons sometimes skip cycles, the population of bushy cells encodes the timing of low-frequency sounds and its frequency with every cycle. Comparison of the timing of action potentials of bushy cells at the two sides reveals the ITDs (slanted black lines).

B. Interaural time differences can be detected with delay lines. If axons have systematically differing lengths, their action potentials reach the nearest terminals before they reach the farthest ones. An array of neurons that detects coincident inputs from delay lines can produce a map of ITDs. When sounds come from the right, action potentials from the right ear must be delayed to compensate for the fact that they arrive earlier than those from the left and to allow the signals from right and left to coincide at one side of the array (mustard-colored cell). Such an arrangement of delay lines has been found in the nucleus laminaris of the barn owl, the homolog of the medial superior olivary nucleus.

Olivocochlear neurons form a feedback loop from the superior olivary complex to hair cells in the cochlea. Their cell bodies lie around the major dense clusters of cell bodies in the olivary nuclei. In mammals two groups of olivocochlear neurons have been distinguished. The medial olivocochlear neurons have myelinated axons that terminate on the outer hair cells bilaterally; the lateral olivocochlear neurons have unmyelinated axons that terminate ipsilaterally on the afferent fibers associated with inner hair cells.

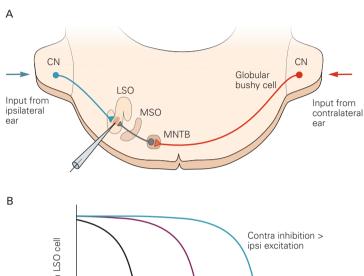

Most medial olivocochlear neurons, with cell bodies that lie ventral and medial within the olivary complex, send their axons to the contralateral cochlea (Figure 31–7), but many also innervate the ipsilateral cochlea. These cholinergic neurons act on hair cells through a special class of nicotinic acetylcholine receptor-channels formed from α9 and α10 subunits. Calcium ions that enter through these channels activate K⁺ channels that hyperpolarize outer hair cells. These neurons thus mediate negative feedback and are binaural, being driven predominantly but not exclusively by stellate cells of the contralateral ventral cochlear nucleus. Collateral branches of olivocochlear neurons terminate on stellate cells in the cochlear nucleus, acting on conventional nicotinic and muscarinic acetylcholine receptors, forming an excitatory feedback loop. Activity in these efferent fibers increases the representation of signals in noise, reduces the sensitivity of the cochlea, and protects it from damage by loud sounds.

C. Mammals use delay lines on the contralateral side only to form a map of interaural time differences. The bitufted neurons of the medial superior olivary nucleus form a sheet that is contacted on the lateral face by bushy cells from the ipsilateral cochlear nucleus and on the medial face by bushy cells from the contralateral cochlear nucleus. On the ipsilateral side the branches of the bushy cell axon are of equal length and thus deliver synaptic currents to their targets in the medial superior olive simultaneously. On the contralateral side the branches deliver synaptic currents first to the anterior regions, closest to the midline, and then to progressively more posterior regions. The postsynaptic neurons can detect synchronous excitation only when sounds arise from the contralateral half of space. When sounds arise from the right side, their early arrival at the right ear is compensated by progressively later arrival at neurons in the posterior region of the left medial superior olive (the mustard-colored cell is activated by a sound from the far right, as in part B). When sounds arise from the front and there is no interaural time difference, neurons in the anterior end of the medial superior olive are activated synchronously from both sides. Thus each medial superior olive forms a map of where sounds arise in the contralateral hemifield. (Adapted, with permission, from Yin 2002.)

Figure 31–6 Interaural intensity differences localize sound sources in the horizontal plane.

A. Principal cells of the lateral superior olivary nucleus (LSO) receive excitatory input from the ipsilateral cochlear nucleus (CN) and inhibitory input from the contralateral cochlear nucleus. A coronal section through the brain stem of a cat illustrates the anatomical connections. Small spherical bushy cells and stellate cells in the ipsilateral ventral cochlear nucleus provide direct excitation. Globular bushy cells in the contralateral ventral cochlear nucleus project across the midline and excite neurons in the medial nucleus of the trapezoid body (MNTB) through large terminals, the calyces of Held. Cells of the medial nucleus of the trapezoid body inhibit neurons in both the lateral superior olive and medial superior olive (MSO). For neurons of the lateral superior olive to compare intensities of the same sound, the timing of the ipsilateral excitatory input must be matched with the timing of the contralateral inhibitory input. To this end globular bushy cells have particularly large axons and synaptic transmission through a calyx of Held in the medial nucleus of the trapezoid body is strong so that the synaptic delay is short and invariant in its timing.

B. The firing of neurons in the lateral superior olive reflects a balance of ipsilateral excitation and contralateral inhibition. For any particular neuron, when sounds arise from the ipsilateral side, excitation is relatively stronger and inhibition is relatively weaker than when sounds arise from the contralateral side. The transition between the dominance of excitation and inhibition varies between neurons (black, red, blue) so that firing in the population of neurons reflects the location of the sound source.

Contra inhibition > ipsi excitation > ipsi excitation |

Ipsi excitation > contra inhibition |

Ipsilateral | Contralateral |

Location of sound source

Lateral olivocochlear neurons, with cell bodies that lie in and around the lateral superior olive, send their unmyelinated axons exclusively to the ipsilateral cochlea, where they terminate on the afferent fibers from inner hair cells. These efferents balance the excitability of cochlear nerve fibers at the two ears.

Brain Stem Pathways Converge in the Inferior Colliculus

The inferior colliculus occupies a central position in the auditory pathway of all vertebrate animals because all auditory pathways ascending through the brain stem converge there (Figure 31–7). The most important sources of excitation are stellate cells of the contralateral ventral cochlear nucleus, fusiform cells of the contralateral dorsal cochlear nucleus, principal cells of the ipsilateral medial superior olive and contralateral lateral superior olive, principal cells of ipsi- and contralateral dorsal nuclei of the lateral lemniscus, commissural

connections from the contralateral inferior colliculus, and pyramidal cells in layer V of the auditory cortex. Important sources of inhibition include the nuclei of the lateral lemniscus, the ipsilateral lateral superior olive, the superior paraolivary nucleus, and the contralateral inferior colliculus.

The inferior colliculus of mammals is subdivided into the central nucleus, dorsal cortex, and external cortex. The central nucleus is tonotopically organized. All neurons in each lamina have similar best frequencies. Low frequencies are represented dorsolaterally and high frequencies ventromedially. Fine mapping has shown that the tonotopic organization is discontinuous; the separation between best frequencies corresponds to psychophysically measured critical bands of approximately one-third octave. Although the central nucleus is organized tonotopically, the spectral range of inputs to these neurons is broader than at earlier stages in the auditory pathway. Inhibition sharpens the frequency tuning of inferior colliculus excitatory

neurons, and tuning can be further modulated by descending inputs from the cortex.

Many neurons in the central nucleus carry information about the location of sound sources. The majority of these cells are sensitive to interaural time and intensity differences, which are known to be essential cues for localizing sounds in the azimuth. Neurons are also sensitive to spectral cues that localize sounds in the vertical plane (see Figure 31–1B). To localize sounds accurately, animals must ignore the reflections of sounds from surrounding surfaces that arrive after the initial direct wave front. Psychophysical experiments have shown

that mammals suppress all but the earliest versions, a phenomenon termed the *precedence effect*. Physiological correlates of the precedence effect have been measured in the inferior colliculus, where inhibition suppresses simulated reflections of sounds.

Sound Location Information from the Inferior Colliculus Creates a Spatial Map of Sound in the Superior Colliculus

The inferior colliculus is not only a convergence point but also a branch point for ascending or outflow pathways.

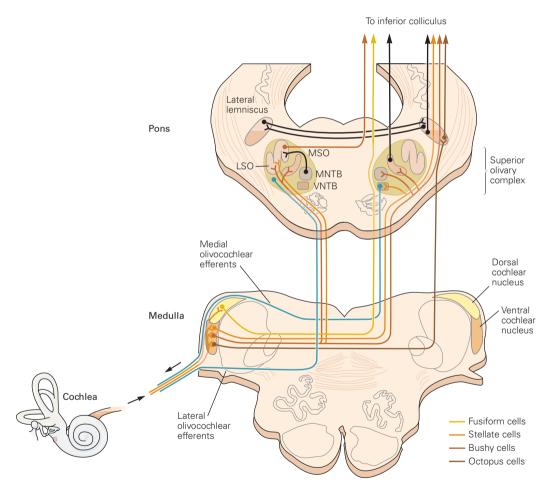

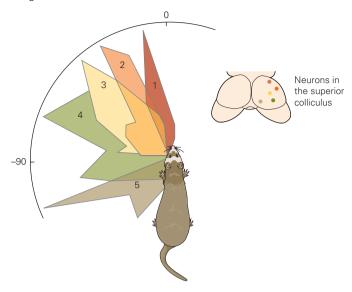

Figure 31–7 Major components of the ascending and descending auditory pathways. The major connections among the nuclei that form the early auditory pathway are shown; because the auditory pathway is bilaterally symmetrical, only one side is illustrated. The ascending pathway begins in the cochlea and progresses through several parallel pathways through the brain stem cochlear nuclei: the cochlear nuclei, the superior olivary nuclei, and the ventral and dorsal nuclei of the lateral lemniscus. These signals converge in the inferior colliculus,

which projects to the medial geniculate body of the thalamus and thence to the cerebral cortex (see Figure 31–2). Some of the connections are excitatory pathways (colored lines) and others inhibitory pathways (black lines). These same nuclei are also interconnected through descending pathways (blue lines) and through commissural projections. (LSO, lateral superior olivary nucleus; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olive; VNTB, ventral nucleus of the trapezoid body.)

A Directional tuning of neurons in the ferret

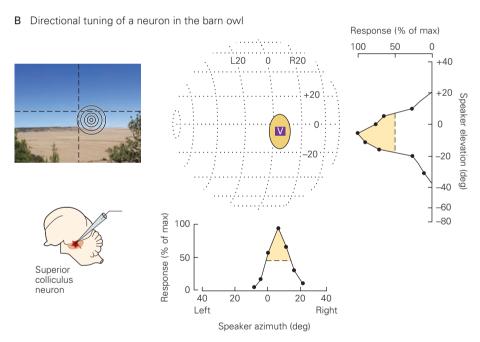

Figure 31–8 Sound localization in the superior colliculus.

A. Neurons in the ferret's superior colliculus are directionally tuned to sound in the horizontal plane. The colored areas represent the firing rate response profiles of collicular neurons 1 through 5 as a function of where the sounds are located, plotted in polar coordinates centered on the head. The inset shows the location of the recorded neurons in the colliculus. Note that neuron 1 responds best to sounds in front of the animal, whereas the responses of neurons that are located progressively more caudally in the colliculus shift correspondingly to sounds that originate farther contralaterally. The location of the sound begins in front of the animal at 0 degrees and moves contralaterally to a point beyond –90 degrees. (Modified, with permission, from King 1999.)

B. The normalized responses of a neuron in the barn owl's superior colliculus to noise bursts presented at various locations along

the horizon or at various elevations are plotted below and at the right, respectively. The yellow areas in these tuning curves indicate where responses exceed 50% of the maximum. The sensitivity of the neuron to a particular location along the horizon as well as a particular elevation creates a discrete best auditory area in space for this neuron, shown as the ellipse labeled "V" on a plot of spatial locations with respect to a point straight in front of the owl. The neuron also responds to visual cues from the same area in space. The photograph illustrates the neuron's best area in space with respect to the position of the head; the intersection of the dashed lines indicates where the owl's head is pointing; photo reproduced, with permission, from Malia Jensen (Modified, with permission, from Cohen and Knudsen 1999.)

Central nucleus neurons project to the thalamus and also to the external cortex of the inferior colliculus and the nucleus of the brachium of the inferior colliculus, both of which then project to the superior colliculus (or the optic tectum in birds).

The superior colliculus is critical for reflexive orienting movements of the head and eyes to acoustic and visual cues in space. By the time they reach the superior colliculus, binaural sound cues and the monaural spectral cues that underlie mammalian sound localization merge to create a spatial map of sound, an auditory map, in which neurons are unambiguously tuned to specific sound directions. This convergence is critical, for the binaural level and timing differences alone cannot unambiguously code for a single position in space. The spectral cues that provide information about vertical location are essential. Different locations in the vertical plane can give rise to identical interaural time or intensity differences. Such a spatial map is formed both in birds and in some mammals (Figure 31-8). In ferrets and guinea pigs topographic representations of the location of sound in the horizontal plane are found in the external cortex and the nucleus of the brachium of the inferior colliculus.

Within the superior colliculus the auditory map is congruent with maps of visual space and the body surface. Unlike the visual and somatosensory maps, the auditory map is computed from a combination of cues that identify the specific position of a sound source in space, and is not based on the peripheral receptor surface.

Auditory, visual, and somatosensory neurons in the superior colliculus all converge on output pathways in the same structure that controls orienting movements of the eyes, head, and external ears. The motor circuits of the superior colliculus are mapped with respect to motor targets in space, and are aligned with the sensory maps. Such sensory-motor correspondence facilitates the sensory guiding of movements.

Midbrain Sound-Localization Pathways Are Sensitive to Experience in Early Life

Cues for sound localization vary both within and across individuals as a result of differences in the size and shape of the head and ears. Moreover, the neural representation of these cues can also vary during development and with changes of the brain as a result of aging. The neural system for sound localization, especially in barn owls, has become an important model for the study of synaptic plasticity in the brain.

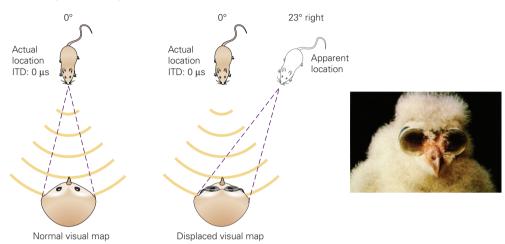

In addition to studies of normal development of sound localization, artificial manipulations of sensory experience have been particularly revealing. In adult mammals and birds occlusion of one ear alters the binaural acoustic cues and causes mislocalization of sounds toward the open ear. When such manipulations of sound cues are conducted in young owls, the animals initially misorient but recover accurate orienting responses over a period of weeks. This is accompanied by a shift in the tuning of auditory neurons in the colliculi toward the abnormal cues that result from use of the earplug. If the earplug is removed after adaptation, owls initially make orienting errors in the opposite direction, but gradually recover accurate behavior as well as a normal spatial map of sound in the brain.

Because visual and auditory cues are normally in alignment in the external world, their representations are also congruent in the superior colliculus (Figure 31–8B). Alterations of visual inputs, and thus of the normal match between acoustic and visual cues, also affect sound localization. When carried out early in development, such visual manipulations cause striking changes in the spatial mapping of sound in the colliculi. For example, when an eye is deviated laterally in a young ferret by removal of an extraocular muscle, the auditory map in the contralateral superior colliculus undergoes a shift so that the visual and auditory maps remain in alignment.

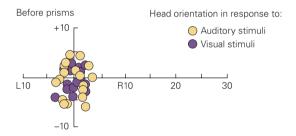

In barn owls, which cannot move their eyes, the visual field has been experimentally misaligned by raising owls with prisms that shift the visual world horizontally (Figure 31–9A). Over the course of weeks owls adjust their auditory orienting responses so that their movements correspond to the location of a target in the shifted visual space. Although the response to sounds is incorrect in terms of purely auditory cues, this is an adaptive response because it causes the animal to look at the source of the sound. In parallel with the changes in behavior, neurons in the colliculi gradually shift their response to interaural time differences by the amount of displacement in the visual field (Figure 31–9B).

The mechanisms of this plasticity, which may be very general, have been extensively studied by Eric Knudsen and his colleagues. The auditory map in the central nucleus of the inferior colliculus does not change in young owls reared with prisms. However, orderly axonal connections from the central nucleus to the external nucleus gradually sprout, forming a pathway that represents the newly learned interaural timing difference (Figure 31–10). The original inputs from the central nucleus persist but are actively suppressed by GABA-ergic inhibitory inputs. The retention of the old functional connections likely underlies the rapid

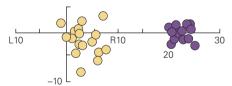

A Prisms displace visual space

B Prisms alter auditory orienting behavior

Soon after prism displacement of the visual field 23° right

42 days after displacement

Soon after prisms removed

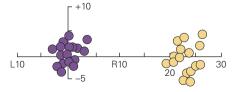

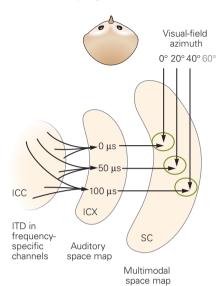

Figure 31–9 The sensitivity of sound localization to experience.

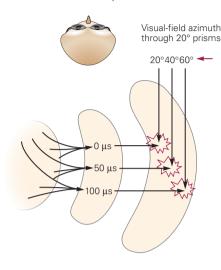

A. The diagrams show the normal relationship of sounds and visual cues for a juvenile barn owl and the disturbance of this correspondence by prisms that shift the visual field 23 degrees. Normally when a mouse is at the center of the visual field the sounds arrive at the two ears simultaneously; with the prisms, when the mouse is seen 23 degrees to the right of the visual-field center, the sounds nevertheless are perceived to originate at the true location of the rodent (0 degrees) and are therefore mismatched with visual perception. Reinterpreting the sound cues as being shifted to the right reestablishes the correspondence between visual and auditory cues. (ITD, interaural time delay.) (Modified, with permission, from Brainard and Knudsen 1993.)

B. Plots of a barn owl's head movements in response to visual and auditory cues before and after wearing prisms. Normally sounds and sights from the center of the visual field (0°,0°) make the animal point its head at that location. When the animal is fitted with prisms that shift the visual field 23 degrees to the right, it turns its head to the central location in response to sound but looks 23 degrees to the right (the shifted location) for a centrally located visual cue. In time the owl shifts its head movements to the right by 23 degrees when it hears a centrally located sound, so that they correspond with head movements made in response to the shifted visual cues. A plot of head movements shortly after the prisms are removed, when both visual and auditory cues are again veridical, reveals the locus of plasticity: The animal's mapping of sounds has shifted, whereas the map of visual cues is unchanged.

2 Prisms create mismatch of auditory and visual receptive fields

3 Auditory remapping realigns receptive fields

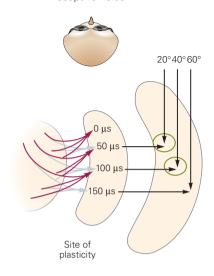

Figure 31–10 The neural locus of plasticity in sound localization. The neural pathway for sound localization originates in the central nucleus of the inferior colliculus (ICC), extends to the external nucleus of the inferior colliculus (ICX), and from there to the superior colliculus (SC), also known as the optic tectum. (Modified, with permission, from Knudsen 1999.) 1. Neurons tuned to interaural time delays (ITDs) from many different frequency bands in the central nucleus normally converge on the external nucleus in a topographic manner to create a systematic map of space based on sound cues (here only the map from 0 μs to 100 μs is shown for simplicity). This

map is then relayed to the superior colliculus, where it is in register with the visual map (circles). 2. In the prism-reared owl the shift in the visual field initially creates a mismatch in the superior colliculus between the auditory and visual maps. 3. In time the inferior colliculus axons sprout collaterals (burgundy) that create a shifted map of space within the external nucleus. This shifted map, when relayed to the superior colliculus, is now in register with the shifted visual map. The original projections persist but are actively suppressed.

restoration of normal tuning after the prisms have been removed.

The prism experiments illustrate that vision plays a dominant role in changes in synaptic function in the auditory system. As further evidence for this idea, a small lesion in the superior colliculus prevents synaptic changes in the corresponding area of the inferior colliculus to accommodate prism displacement. Presumably the same instructive signals from the superior colliculus guide the transformation of auditory cues into a well-aligned spatial map of sounds during normal development.

A striking aspect of plasticity in both birds and mammals is the sensitivity of the spatial map to an animal's age. As in many other systems there is a critical period in which altered sensory experience can alter the brain and behavior. Marked adaptive changes in orienting behavior are seen in juvenile owls, ferrets, and guinea pigs but ordinarily not in adults. However, learning in young animals increases the capacity for plasticity in

adults. If juvenile owls are subjected to a period of prism displacement but then returned to normal vision, they are capable of reacquiring the shifted map and the corresponding behavior when exposed to the same prism displacement as adults. However, their inferior colliculus cannot acquire a map to which they were not exposed to as juveniles. The period of early learning thus leaves a specific and permanent trace in the nervous system.

An animal's motivational state is also important in how malleable its brain is. If adult barn owls fitted with prisms are allowed to hunt for live mice, a more arousing situation than typical laboratory conditions, they display behavioral and neural plasticity intermediate between that of normally housed adults and juveniles. Similar increases in sensory plasticity have been seen in mammals actively involved in tasks that require specific sensory information. This suggests the clinically important point that more plasticity can be elicited from the adult brain if attention and motivation can be engaged appropriately.

The Inferior Colliculus Transmits Auditory Information to the Cerebral Cortex

Auditory information ascends to the cerebral cortex through the thalamus. Neurons of the inferior colliculus project to the medial geniculate body, where principal cells in turn project to the auditory cortex. The pathways from the inferior colliculus include a lemniscal or core pathway and extralemniscal or belt pathways. Descending projections from the auditory cortex to the medial geniculate body are prominent both anatomically and functionally.

The Auditory Cortex Maps Numerous Aspects of Sound

Ascending auditory pathways terminate in the auditory cortex, which includes multiple distinct areas on the dorsal surface of the temporal lobe. The most prominent projection is from the ventral division of the medial geniculate nucleus to the primary auditory cortex (A1, or Brodmann area 41). As in the lower relays of auditory processing, this cytoarchitectonically distinct region contains a tonotopic representation of characteristic frequencies: Neurons are arrayed in a systematic map reflecting the frequencies that best stimulate them. Neurons tuned to low frequencies are found at the rostral end of A1, and those responsive to high frequencies in the caudal region (Figure 31-11). Thus, like the visual and somatosensory cortices, the primary auditory cortex contains a map reflecting the pattern of peripheral sensors.

Because the cochlea encodes only frequency, however, a one-dimensional map from the periphery is spread across the two-dimensional surface of the cortex, with a smooth frequency gradient in one direction and iso-frequency contours along the other direction. In many animals subregions of the auditory cortex representing biologically significant frequencies are enlarged because of extensive inputs, similar to the large area in the primary visual cortex devoted to inputs from the fovea.

In addition to frequency, other features of auditory stimuli are mapped in the primary auditory cortex, although the overall organization is less clear and precise than for vision. Auditory neurons in A1 are excited by input from both ears (EE), with the contralateral input usually stronger than the ipsilateral contribution, or by unilateral input (EI). The EI neurons are inhibited by stimulation of the opposite ear. Summation columns of EE neurons alternate with suppression columns of EI neurons, especially in the high-frequency portion of A1, creating a map of interaural interactions

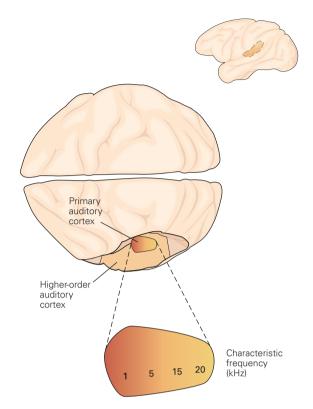

Figure 31–11 The auditory cortex of primates has multiple primary and secondary areas. The expanded figure shows the major tonotopic map of the primary auditory cortex. The primary areas are surrounded by higher-order areas (see Figure 31–13).

at right angles to the axis of tonotopic mapping. This partitions the auditory cortex into columns responsive to every audible frequency and each type of binaural interaction.

Certain neurons in A1 also seem to be organized according to bandwidth, that is, according to their responsiveness to a narrow or broad range of frequencies. Distinct subregions of A1 form clusters of cells with narrow or broadband tuning within individual iso-frequency contours. Synaptic connections within the cortex respect these clusters, with neurons receiving intracortical input primarily from neurons with similar bandwidths and characteristic frequencies. This modular organization of bandwidth selectivity may allow redundant processing of incoming signals through neuronal filters of varying bandwidths as well as center frequencies, which could be useful for the analysis of spectrally complex sounds such as species-specific vocalizations, including speech.

Several other parameters are mapped on the surface of A1. These include neuronal response latency,

loudness, modulation of loudness, and the rate and direction of frequency modulation. Although it remains to be seen how these various maps intersect, this array of parameters clearly endows each neuron and each location in A1 with the ability to represent many independent variables of sound and generates a great diversity of neuronal selectivity.

As is true for visual and somatosensory areas of the cortex, sensory representation in A1 can change in response to altered input. After peripheral hearing loss, tonotopic mapping can be altered so that neurons originally responsive to sounds within the range of the hearing loss begin to respond to adjacent frequencies. The work of Michael Merzenich and others has shown that behavioral training of adult animals can also result in large-scale reorganization of auditory cortex, so that the most behaviorally relevant frequencies—those specifically associated with attention or reinforcement—come to be overrepresented.

The auditory areas of young animals are particularly plastic. In rodents the frequency organization of A1 emerges gradually during development from an early, crude frequency map. Raising animals in acoustic environments in which they are exposed to repeated tone pulses of a particular frequency results in a persistent expansion of cortical areas devoted to that frequency, accompanied by a general deterioration and broadening of the tonotopic map. This result not only suggests that the development of A1 is experience-dependent, but raises the possibility that early exposure to abnormal sound environments can create long-term disruptions of high-level sensory processing. A greater understanding of how this happens and whether it is also true for human fetuses and infants may provide insights into the origin and remediation of disorders in which auditory processing is centrally impaired, such as many forms of dyslexia. Moreover, the ability to induce synaptic changes in adult auditory cortex by engaging attention or reward raises new hopes for brain repair even in adulthood.

Auditory Information Is Processed in Multiple Cortical Areas

The primary auditory area of mammals is surrounded by multiple distinct regions, many of which are tonotopic. These highly tonotopic areas resemble A1 in that they receive direct input from the ventral division of the medial geniculate nucleus. Like the major thalamocortical visual projection, this input primarily contacts cortical layers IIIb and IV. Adjacent tonotopic fields have mirror-image tonotopy: The direction of tonotopy reverses at the boundary between fields.

As many as 7 to 10 secondary (belt) areas surround 3 to 4 primary or primary-like (core) areas (see Figure 31–13). These cortical areas receive input from the core areas of auditory cortex and in some cases from thalamic nuclei. Electrophysiological and imaging studies have confirmed that the primary auditory cortex in humans lies on Heschl's gyrus, in the temporal lobe, medial to the sylvian fissure. In addition, recent functional magnetic-resonance imaging studies have revealed that in humans, just as in monkeys, pure tones activate primarily core regions, whereas the neurons of belt areas prefer complex sounds such as narrow-band noise bursts.

Insectivorous Bats Have Cortical Areas Specialized for Behaviorally Relevant Features of Sound

Although it is generally assumed that the upstream auditory areas perform increasingly specialized functions related to hearing, our knowledge about the functions of serial relays is much less in the auditory system than the visual system. In humans one of the most important aspects of audition is its role in processing language, but we know relatively little about how speech sounds are analyzed by neural circuits. New techniques for imaging the human brain are gradually providing insights into the localization of cortical areas associated with language (see Chapter 60).

The best evidence for specialized analysis of complex auditory signals in auditory cortical areas comes from studies of insectivorous bats. These animals find their prey almost entirely through *echolocation*, emitting ultrasonic pulses of sound that are reflected by flying insects. Bats analyze the timing and structure of the echoes to help locate and identify the targets, and discrete auditory areas are devoted to processing different aspects of the echoes.

Many bats, such as the mustached bat studied by Nobuo Suga and his collaborators, emit echolocating pulses with two components. An initial *constant-frequency* (CF) component consists of several harmonically related sounds or *harmonics*. These harmonics are emitted stably for tens to hundred of milliseconds, akin to human vowel sounds. The constant-frequency component is followed by a sound that steeply decreases in frequency, the *frequency-modulated* (FM) component, which resembles the rapidly changing frequencies of human consonants (Figure 31–12A).

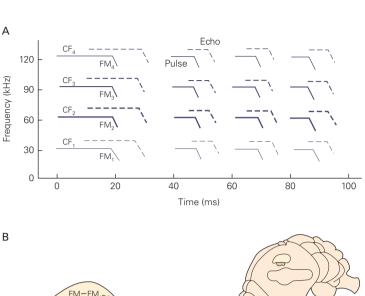

The FM sounds are used to determine the distance to the target. The bat measures the interval between the emitted sound and the returning echo, which corresponds to a particular distance, based on the relatively constant speed of sound. Neurons in the FM-FM area

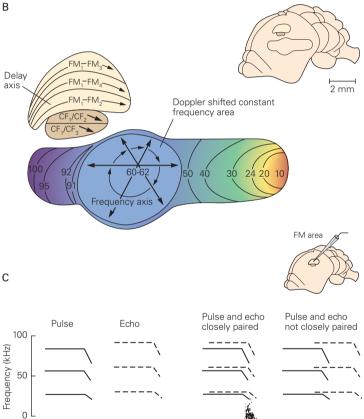

Figure 31–12 The auditory system of the bat has specialized areas for locating sounds.

A. A sonogram of an animal's calls (solid lines) and the resultant echoes (dashed lines) illustrates the two components of the call: the protracted, harmonically related constant-frequency (CF) signal and the briefer frequency-modulated (FM) signal. The duration of the calls decreases as the animal approaches its target.

B. A view of the cerebral hemisphere of the mustached bat shows three of the functional areas within the auditory cortex. The FM area is where the distance from the target is computed; the CF area is where the velocity of the target is computed; and the Doppler-shifted CF area is specialized for the identification of small fluttering objects. The expanded cortical representation of Doppler-shifted CFs near the second harmonic of the call frequency (60 to 62 kHz) forms the acoustic "fovea."

C. An FM-FM combination-sensitive neuron does not respond significantly to either pulses or echoes alone, but responds very strongly to a closely paired pulse and echo. However, the neuron is also sensitive to the time difference between the pulse and echo, as seen in the record on the right, where the neuron fails to respond to a pulse-echo combination that is not closely paired. (Modified, with permission, from Suga et al. 1983).

of auditory cortex (Figure 31–12B) respond preferentially to pulse-echo pairs separated by a specific delay. Moreover, these neurons respond better to particular combinations of sounds than to the individual sounds in isolation; such neurons are called *feature detectors* (Figure 31–12C). The FM-FM area contains an array of such detectors, with preferred delays systematically ranging from 0.4 ms to 18 ms, corresponding to target ranges of 7 cm to 310 cm, mapped along the cortical

surface (see Figure 31–12B). These neurons are organized in columns, each of which is responsive to a particular combination of stimulus frequency and delay. In this way the bat, like the barn owl in its inferior colliculus, is able to represent an acoustic feature that is not directly represented by sensory receptors.

The CF components of bat calls are used to determine the relative speed of the target with respect to the bat and the acoustic image of the target. When an

echolocating bat is flying toward an insect, the sounds reflected from the insect are Doppler-shifted to a higher frequency at the bat's ear, for the bat is moving toward the returning sound waves from the target, causing a relative speeding up of these waves at its ear. Similarly, a receding insect yields reflections of lowered frequency at the bat's ear. Neurons in the CF-CF area (see Figure 31–12B) are sharply tuned to a combination of frequencies close to the emitted frequency or its harmonics. Each neuron responds best to a combination of a pulse of a particular fundamental frequency and an echo corresponding to the first or second harmonic of the pulse, Doppler-shifted to a specific extent. As in the FM-FM area, neurons do not respond to the pulse or echo alone, but rather to the combination of the two CF signals.

CF-CF neurons are arranged in columns, each encoding a particular combination of frequencies. These columns are arranged regularly along the cortical surface, with the fundamental frequency along one axis and the echo harmonics along a perpendicular axis. This dual-frequency coordinate system creates a map wherein a specific location corresponds to a particular Doppler shift and thus a particular target velocity, ranging systematically from -2 m/s to 9 m/s.

The CF components of returning echoes are also used for detailed frequency analysis of the acoustic image, presumably important in its identification. The Doppler-shifted constant-frequency area (DSCF) of the mustached bat is a dramatic expansion of the primary auditory cortex's representation of frequencies between 60 kHz and 62 kHz, corresponding well to the set of returning echoes from the major CF component of the bat's call (see Figure 31–12B). Within the DSCF area individual neurons are extremely sharply tuned to frequency, so that the tiny changes in frequency created by fluttering moth wings are easily detected.

Transient inactivation of some of these specialized cortical areas, while the bat performs a discrimination task, strikingly supports the importance of their functional specialization in behavior. Silencing of the DSCF selectively impairs fine frequency discrimination while leaving time perception intact. Conversely, inactivation of the FM-FM area impairs the bat's ability to detect small differences in the time of arrival of two echoes, while leaving frequency perception unchanged.

Investigation of this auditory system was greatly facilitated by knowledge of the stimuli relevant to bats. It remains to be seen whether these cortical areas are functionally or anatomically analogous to particular fields in cats, monkeys, and humans. Regardless, ethologically significant stimuli are likely to be as useful

in studying these other species as they have been in studies of bats.

A Second Sound-Localization Pathway from the Inferior Colliculus Involves the Cerebral Cortex in Gaze Control

Many auditory neurons in the cerebral cortex are sensitive to interaural time and level differences and therefore to the location of sounds in space. Most of these cells have large receptive fields and broad tuning. In contrast to the auditory relays in the midbrain, however, there is no evidence for an organized spatial map of sound in any of the cortical areas sensitive to sound location.

The sound-localization pathways in the cortex originate in the central nucleus of the inferior colliculus and ascend through the auditory thalamus, area A1, and cortical association areas, eventually reaching the frontal eye fields involved in gaze control. Eye or head movements can be elicited by stimulating the frontal eye fields, which connect directly to brain stem tegmentum premotor nuclei that mediate gaze changes, as well as to the superior colliculus. But the midbrain pathway from location-sensitive neurons in the inferior colliculus to the superior colliculus to gaze-control circuitry can directly regulate orientation movements of the head, eyes, and ears. Why should there be a second sound-localization pathway connected to gaze-control circuitry?

Behavioral experiments shed light on this question. Although lesions of A1 can result in profound sound-localization deficits in a monkey, no deficiency is seen when the task is simply to indicate the side of the sound source by pushing a lever. The deficit becomes apparent only when the animal must approach the location of a brief sound source, that is, when the task is the more complex one of forming an image of the source, remembering it, and moving toward it.

Experiments in barn owls have produced particularly compelling evidence. The ability of owls to orient to sounds in space is unaffected by inactivation of the avian equivalent of the frontal eye fields. Similarly, when the midbrain localization pathway is disrupted by pharmacological inactivation of the superior colliculus, the probability of an accurate head turn is decreased but animals still respond correctly more than half of the time. In contrast, when both structures are inactivated, animals are completely unable to orient accurately to acoustic stimuli on the contralateral side. Thus cortical and subcortical sound-localization pathways have parallel access to gaze control centers, perhaps providing some redundancy. Moreover, when

only the frontal eye fields are inactivated, birds lose their ability to orient their gaze toward a target that has been extinguished and must be remembered, just as is seen with mammalian A1 lesions. Thus in both mammals and birds cortical pathways are required for more complex sound-localization tasks.

This appears to be a general difference between cortical and subcortical pathways. Subcortical circuits are important for rapid and reliable performance of behaviors that are critical to survival. Cortical circuitry allows for working memory, complex recognition tasks, and selection of stimuli and evaluation of their significance, resulting in slower but more differentiated performance. Examples of this also exist in auditory pathways not involved in localization. Conditioned fear responses to simple auditory stimuli are mediated by direct rapid pathways from the auditory thalamus to the amygdala; they can be elicited after cortical inactivation. However, fear responses that require more complex discrimination of auditory stimuli require pathways through the cortex, and are accordingly slower but more specific.

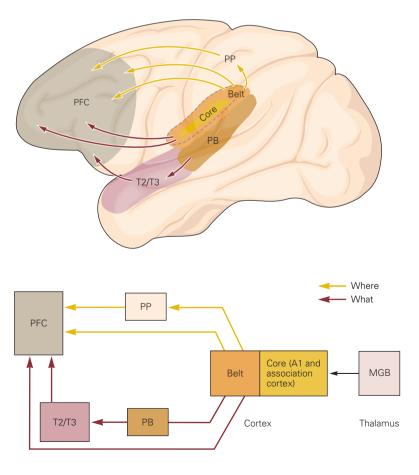

Auditory Circuits in the Cerebral Cortex Are Segregated into Separate Processing Streams

In the visual system the output from the primary visual cortex is segregated into separate dorsal and ventral streams concerned respectively with object location in space and object identification. A similar division of labor is thought to exist in the somatosensory cortex, and recent evidence suggests that the auditory cortex follows this plan.

Anatomical tracing studies of the three most accessible belt areas in primates show that the more rostral and ventral areas connect primarily to the more rostral and ventral areas of the temporal lobe, whereas the more caudal area projects to the dorsal and caudal temporal lobe. In addition, these belt areas and their temporal lobe targets both project to largely different areas of the frontal lobes (Figure 31–13).

The frontal areas receiving anterior auditory projections are generally implicated in nonspatial functions, whereas those that are targets of posterior auditory areas are implicated in spatial processing.

Figure 31–13 The "what" and "where" streams in the auditory cortical system of primates. The ventral "what" stream and dorsal "where" stream originate in different parts of primary and belt cortex and ultimately project to distinct regions of prefrontal cortex through independent paths. (MGB, medial geniculate body of the thalamus; PB, parabelt cortex; PFC, prefrontal cortex; PP, posterior parietal cortex; T2/T3, areas of temporal cortex.) (Modified, with permission, from Rauschecker 2000 and from Romanski and Averbeck 2009.)

Electrophysiological and imaging studies provide support for this. Caudal and parietal areas are more active when a sound must be located or moves, and ventral areas are more active during identification of the same stimulus or analysis of its pitch. Consistent with this segregation, inactivation of the posterior auditory field in cats impairs performance of a sound-localization task, whereas inactivation of the anterior auditory field interferes with a pattern-discrimination task, but not vice versa. Thus anterior-ventral pathways may identify auditory objects by analyzing spectral and temporal characteristics of sounds, whereas the more dorsal-posterior pathways may specialize in sound-source location, detection of sound-source motion, and spatial segregation of sources.

Although the idea that all sensory areas of the cerebral cortex initially segregate object identification and location is attractive, it is likely an oversimplification. It is clear that the medial-belt areas of the auditory cortex project to both dorsal and ventral frontal cortices, and neurons with broad spatial responsiveness are distributed throughout caudal and anterior areas. Imaging studies with more complex stimuli suggest that parietal pathways are involved in additional functions, including analysis of the temporal properties of acoustic stimuli such as spectral motion. The latter property might explain the clear role of the posterior pathway in speech perception in humans. Nonetheless, although the details may differ between systems, the basic concept holds that sensory systems decompose stimuli into features and analyze these in discrete pathways.

The Cerebral Cortex Modulates Processing in Subcortical Auditory Areas

An intriguing feature of all mammalian cortical areas, and one shared by the auditory system, is the massive projection from the cortex back to lower areas. There are almost 10-fold as many corticofugal fibers entering the sensory thalamus as there are axons projecting from the thalamus to the cortex. Projections from the auditory cortex also innervate the inferior colliculus, olivocochlear neurons, some basal ganglionic structures, and even the dorsal cochlear nucleus.

Insights into possible functions of this feedback have come from the bat's auditory system. Silencing of frequency-specific cortical areas leads to decreased thalamic and collicular responses, whereas activation of cortical projections increases and sharpens the responses of some neurons. The auditory cortex can therefore actively adjust and improve auditory signal processing in subcortical structures.

A variety of evidence suggests that cortical feedback also occurs in the visual and somatosensory components of the thalamus. This challenges the view that ascending sensory pathways are purely feedforward circuits, and suggests that we should regard the thalamus and cortex as reciprocally and highly interconnected circuits in which the cortex exercises some top-down control of perception.

Hearing Is Crucial for Vocal Learning and Production in Both Humans and Songbirds

Virtually all animals use hearing for localization and recognition of sounds, including behaviorally important communication sounds of individuals of the same species (conspecifics), such as mating and warning calls. For animals known as vocal learners, hearing is also necessary for learning to mimic sounds produced by others.

Humans are consummate vocal learners. Human speech involves fantastically complex and variable communication sounds, and we depend critically on hearing the speech both of ourselves and of others for normal speech development. Much is being learned about the auditory areas associated with human speech recognition and production from imaging and electrophysiological techniques. To understand basic brain mechanisms of vocal learning and its disorders, however, it is important to study animals with related behaviors. Surprisingly, there are relatively few other vocal learners.

Although the vocalizations of nonhuman primates can be complex, none have been shown to be learned. Among other mammals there is evidence for vocal learning only in cetaceans (whales and dolphins) and some bats. In striking contrast to this paucity of mammalian vocal learners, the many thousands of songbird species, as well as the parrot and hummingbird groups, all must learn to produce their complex songs. Songbirds have provided a particularly useful model, and there is a wealth of information on their vocal behavior and the underlying brain substrates, with some striking parallels to human speech learning.

Normal Vocal Behavior Cannot Be Learned in Isolation

What do we mean by vocal learning, and how can we demonstrate it? One indication of vocal learning is great variation in the vocal output of a species, such as the multitude of human languages and dialects. Similarly, many songbird species have local dialects (Figure 31–14A), and songs also vary between individual songbirds.

Because such variability could in theory be genetically encoded, a critical test of vocal learning is whether animals develop normal vocal behavior in the absence of hearing other individuals. It is well established that deaf children do not learn to speak normally. In addition, the rare cases of so-called wild children raised without exposure to human speech, such as the girl called Genie, show that speech does not develop normally when hearing is intact but no speech has been heard. In songbirds as well deafness early in life prevents normal song learning and production. Birds reared without exposure to conspecific songs sing highly simplified isolate songs, which nevertheless display some features characteristic of the species (Figure 31–14B, C). In contrast, monkeys reared without exposure to the vocalizations of other monkeys display essentially normal vocal behavior, as do nonsongbirds, such as chickens or flycatchers, deafened or raised in isolation. Clearly both birdsong and speech are learned, with a strong dependence on hearing.

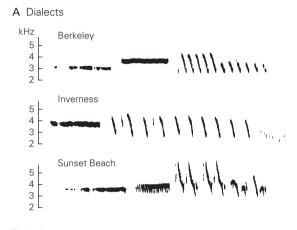

Hearing serves two independent functions in vocal learning. For one, hearing the vocalizations of others allows imitation. This aspect of learning is perceptual in both humans and birds; in songbirds a sensory memory of the tutor's song, often called the template, is rapidly formed and stored during a period called the sensory learning phase. However, neither humans nor songbirds can directly translate their sensory memory of others into a faithful vocal copy. Rather, they initially produce rambling and immature vocalizations, called babbling in humans and subsong in songbirds. They must then be able to hear these vocalizations to gradually refine them and make them match their desired vocal output during a process of sensorimotor learning.

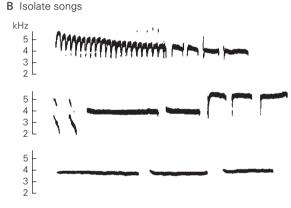

Figure 31-14 Birdsong is learned through mimicry.

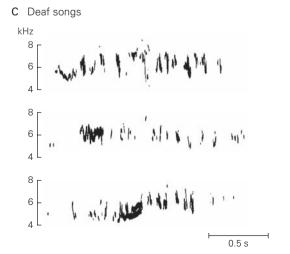

A. Distinct dialects of white-crowned sparrow song are recognizable in these sonograms of recordings from three locations on the northern California coast. Sonograms plot sound frequency against time, with amplitude indicated by density. Common structural elements such as whistles, buzzes, and trills differ in length and frequency in the dialects. Birds learn their dialect early in life from a local tutor, and develop some individual song features as well.

- B. White-crowned sparrows raised without tutors sing isolate songs, which resemble normal sparrow song in duration and whistle-like features but are otherwise much simpler.
- C. Songs of birds that were deaf before sensorimotor learning of song are even more abnormal than isolate songs. This is true whether the animals were tutored or not, so the abnormal song reflects the lack of auditory feedback as birds attempt to produce sounds. (Modified, with permission, from Marler 1970; modified, with permission, from Konishi 1985).

Second, hearing provides vocal learners with sensory information about the accuracy of their motor performance, in the form of auditory feedback. This is especially clear in songbirds. They can memorize adult tutor songs with a relatively small amount of song exposure, and if isolated after such exposure will nevertheless produce a good copy of the tutor song so long as they are able to hear themselves. In contrast, if they are deafened after sensory learning, they produce highly abnormal songs, without even the innate structure usually present in isolate songs (Figure 31-14C). The same dependence on hearing of one's own voice is evident in humans. For instance, the speech of children who become deaf during childhood, even after significant speech learning, deteriorates markedly.

Of course, some aspects of birdsong are clearly not analogous to human speech. Although birdsong is used for communication, it does not seem to be language in the sense of conveying complex meaning. What it shares with speech is the learned sensorimotor control of an elaborate vocal system, with a pronounced dependence on hearing.

Vocal Learning Is Optimal During a Sensitive Period

A variety of evidence makes it clear that neither human nor avian vocal learners are born as "blank slates." Human babies as early as 3 weeks of age can make perceptual distinctions between categories of sounds in languages to which they have never been exposed. For instance, newborn babies in both the United States and Japan can distinguish the sounds "r" and "l," a distinction that does not exist in Japanese and is not well perceived by adult monolingual Japanese speakers (see Chapter 60). Similarly, newly hatched songbirds show innate recognition of and preference for all songs of their own species, relative to other species.

Acoustic experience quickly shapes the nervous system after birth. By 1 year of age children exposed only to Japanese no longer distinguish "r" and "l" sounds, and children being raised in English no longer distinguish the several classes of "h"-like sounds in Hindi or "shi"-like sounds in Mandarin. Similarly, young songbirds quickly begin to learn the songs to which they are actually exposed.

The ability of sensory experience to alter perceptual ability varies with age, as we saw earlier in connection with sound localization. During sensitive or critical periods for learning young children exposed to a language are able to speak the language fluently and without accent. However, their ability to do so

decreases as they grow older. If not exposed to a foreign language by adolescence, most humans cannot learn to speak that language in a manner that is indistinguishable from native speakers, primarily in accent and grammatical usage. This inability seems to reflect decreased perceptual abilities, and not simply limits on the ability to produce the sounds of speech. Songbirds also have clear sensitive periods. In most species birds not exposed to song in the first several months of life go on to sing isolate song even if subsequently exposed to normal adult song; such birds are known as closed learners.

An animal model with sensitive periods for vocal learning like our own can provide insights into the factors that control the synaptic changes, and ultimately the neural mechanisms involved and thus potentially into remediation. For instance, the sensitive period for song learning does not have a strict age limit. Rather, experience itself is centrally involved in closing the sensitive period. Songbirds tutored only with songs from birds of other species (heterospecifics) can incorporate new songs from their own species at a time when birds raised with conspecifics no longer can. In some species birds reared in complete isolation can still incorporate new song elements as adults. Thus a lack of normal experience leaves the brain open to be shaped by the appropriate input for a longer than usual period.

Attentional or motivational factors also influence the timing of the sensitive period. Birds learn from live tutors for longer than they learn from taped tutors. Hormonal factors may play a role as well. Manipulations that delay the onset of singing and decrease testosterone levels appear to extend the sensitive period. In light of this it is intriguing that the human critical period for speech appears to end in adolescence.

Both Humans and Songbirds Possess Specialized Neural Networks for Vocalization

Along with the many behavioral similarities between speech and song learning, both humans and songbirds have evolved specialized neural systems for vocal learning and production. At first glance the very different organization in birds and humans, especially of forebrain areas, seems to make drawing any direct parallels between the two brain systems difficult.

One major difference between birds and humans is that birds do not have the multilayered cortex seen in all mammals, including humans. Rather, the evolutionarily related avian forebrain areas—derived like mammalian cortex from the embryonic region known as the pallium—are organized in nuclei, just as many lower areas are in both mammals and birds. A closer look at

the vocal control systems of humans and songbirds, however, reveals numerous anatomical and functional similarities in the organization of neural pathways for vocal production and processing.

All primates and birds, and many mammals as well, have pathways from midbrain areas to lower respiratory and vocal motor centers as well as medullary centers that integrate respiratory and vocal tract control. Stimulation in these midbrain areas, such as the periaqueductal grey in primates and the dorsomedial intercollicular area in birds, can elicit well-formed vocalizations. However, a critical evolutionary step in the adaptation of learned vocalizations was the development of high-level forebrain areas that control the lower motor pathways for vocalization; both songbirds and humans have such areas whereas nonlearners do not.

In humans numerous perisylvian and parietotemporal cortical areas are critical for speech production, as shown by the effects of lesions and the fact that stimulation of many of these areas can elicit vocalizations or disrupt ongoing speech. In striking contrast, there are no neocortical areas in monkeys from which vocalizations can be elicited by stimulation or whose ablation affects calls. Among birds, only songbirds and other vocal learners such as parrots have evolved an elaborate forebrain system, often called the song system, for control of the lower brain areas involved in vocalization (Figure 31–15A).

The motor control portion of this circuit consists of a chain of nuclei, including in part the premotor nucleus HVC, an erstwhile acronym used as a proper name, which contains a central pattern generator for song. HVC projects to a motor cortex-like area called the robust nucleus of the arcopallium (RA), which then connects to all the lower nuclei involved with vocal motor and respiratory control. Just as in the analogous human areas, stimulation or ablation of HVC or RA dramatically affects song. Moreover, neural recordings demonstrate directly the sequential premotor activity of neurons in these areas during singing.

It has become apparent that, in addition to neocortex or its avian equivalents, the thalamus, basal ganglia, and cerebellum are important in vocal production. Lesion, stimulation, and imaging studies of humans suggest that these areas are involved in fluency, volume, articulation, and rhythm of speech. Whether the cerebellum contributes to birdsong is still unknown, but it is very clear that a specialized loop known as the anterior forebrain pathway connects HVC and RA and is critical for song learning and plasticity throughout life. Numerous recent studies of this circuit are providing insights into the function of the basal ganglia not only in song

plasticity but also in motor learning more generally. These functions include acting as a source of motor variability and biasing signals important for trial-and-error learning and modulating motor output in response to social cues.

Finally, both humans and songbirds have numerous high-level auditory areas associated with processing and recognition of complex vocalizations. Many of the areas described earlier receive such auditory inputs and in fact encompass sensorimotor rather than purely motor circuits. A crucial step in the evolution of specialized vocal control areas may have been the acquisition of auditory input by preexisting motor control areas in the forebrain, giving those auditory inputs the ability to change the vocal motor map. The close relatives of songbirds, the suboscine birds such as flycatchers and phoebes, can sing but display no vocal learning; these birds also show no evidence of a specialized forebrain song-control system. In humans the capacity to learn speech and the development of specialized cortical systems for its control may have resulted from close interaction of motor control areas for orofacial movements with a variety of areas involved in processing and memorizing complex sounds.

Songbirds Have Feature Detectors for Learned Vocalizations

Reflecting the critical importance of hearing in song learning, the song system contains some of the most complex auditory neurons known. The use of behaviorally relevant stimuli, such as the bird's own song and the songs of conspecifics, was critical to the discovery of these remarkable neurons. Song-selective neurons are found throughout the adult male song system and respond more strongly to an animal's own song, and in some cases to the tutor's song, than to other equally complex auditory stimuli, such as conspecific songs or the animal's own song played in reverse or with the syllables out of order (Figure 31–15B).

In addition, many of these neurons are combination-sensitive: They show a highly nonlinear increase in firing when the component sounds of the bird's own song are combined and played in the correct sequence, compared to those sounds played alone (Figure 31–15C). Feature detectors with such marked spectral and temporal sensitivity could provide feedback to song motor areas, in the form of their firing rate or pattern, about how well sounds match the bird's goal and when the correct sequence has been sung. It is tempting to speculate that analogous neurons with responsiveness to well-learned speech sequences exist in humans.

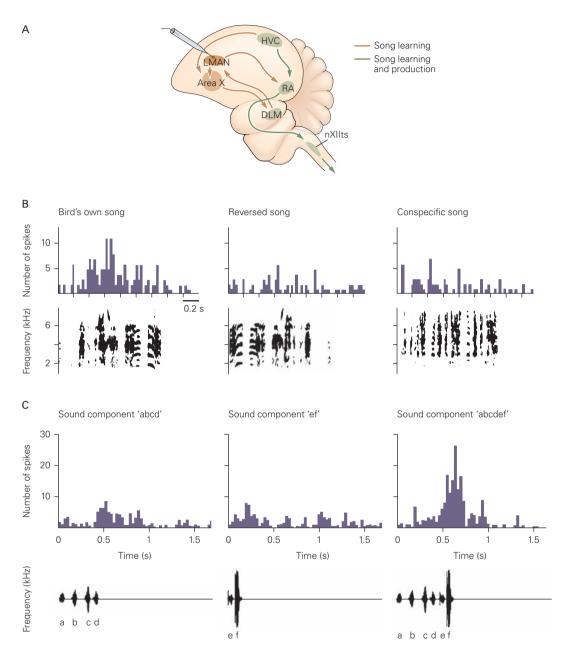

Figure 31–15 Song-selective neurons in the songbird brain.

A. A side view of the songbird brain illustrates some of the major components of the song system. The premotor nucleus HVC and robust nucleus of the arcopallium (RA) form the motor pathway for producing song. The RA motor nucleus projects to peripheral effectors that include the hypoglossal nucleus (nXIIts). The anterior forebrain pathway connects the HVC and RA through the rostral part of the brain, and includes the basal ganglionic nucleus area X, the medial nucleus of the dorsolateral thalamus (DLM), and the lateral magnocellular nucleus of the anterior nidopallium (LMAN), an outflow region that connects back to RA.

- B. Peristimulus time histograms of recordings from an LMAN neuron in an adult zebra finch show that the neuron responds more vigorously to the bird's own song than to a reversed version of the song or even to a conspecific song. The song is displayed beneath each histogram as a sonogram, or plot of frequency against time. Such song-selective neurons are found throughout the song system.
- C. An LMAN neuron is much more sensitive to a complete song "abcdef" than to isolated components "abcd" or "ef". In this panel the song is portrayed as an oscillogram, or plot of sound pressure against time. (Modified, with permission, from Doupe 1997.)

The song selectivity of these songbird neurons is not present in young birds, but emerges during the course of song learning. Early in the sensory learning phase the neurons respond equally well to all conspecific song stimuli. Over time their response to the bird's own song increases while responsiveness to other stimuli declines. In this way the neurons parallel the initial broad acoustic sensitivity of human infants, which is subsequently narrowed and shaped by individual auditory experience.

Song-selective neurons not only respond to complex sensory signals, but can also be active during motor production. For instance, the same neurons that respond to a particular song are also active during singing of the song. These neurons are thus another example of mirror neurons (Chapter 38). Because adult song is such a stereotyped motor act, song neurons may provide insight into the function of mirror neurons. For instance, there is a remarkable correspondence between these song neurons' auditory responses and their premotor activity: playback of one set of syllables triggers an auditory response that resembles the premotor activity for the next syllable in the song. Thus the auditory response could be considered a prediction of the motor command for the following syllable.

The sensorimotor, mirror properties of song-selective neurons raise the possibility that they are critically involved in linking sensory and motor representations in the song system; such action-perception coupling may be the function of mirror neurons more generally. In this intermixing of sensory and motor processing, birdsong is again reminiscent of human speech. Electrical stimulation of a single language area in humans can affect both production and perception of speech, and some cortical neurons respond differently to the same word depending on whether it is spoken by the subject or by someone else. In songbirds it should be possible to explore the mechanisms underlying this sensory-motor interaction.

An Overall View

The central auditory system transforms the firing patterns of eighth-nerve fibers into the neural signals required for the localization and recognition of sounds, and in some animals for shaping vocal output. As in other sensory systems, this processing is accomplished by detecting and extracting different features of sound and analyzing these in separate pathways, only later merging the results.

Sound localization, which is best understood, involves representing information about interaural

timing and level differences and about the amplitude spectrum of sounds that reflects filtering by the ear, and associating these with locations in space in an experience-dependent way. The ability of visual cues to alter sound localization is a potent reminder that sensory systems evolved together to guide behavior: Animals localize sounds in order to find their sources.

Sound recognition is much less understood, and the multiplicity of cortical auditory areas involved suggests that analyzing it will be a challenge. The study of auditory specialists such as bats and their use of natural auditory stimuli has, however, taught us a great deal about what different auditory areas accomplish. This suggests that the continuing use of specialized animals and behaviorally relevant stimuli will be important in future discoveries. For primates, including humans, this will include the study of their own vocalizations. Songbirds, which show complex vocal learning with similarities to human speech acquisition, provide an additional source of insights into neural mechanisms of learning and the developmental regulation of plasticity.

The auditory system is the site of several critical periods, likely including that for speech learning, but can be coaxed into plasticity in adult animals. Demonstrated originally in experimental animals but now applied in humans as well, this result raises hope for new strategies to remediate deficits in human brain function.

Sensory Neurons Carry Taste Information from the Taste Buds to the Brain

Taste Information Is Transmitted from the Thalamus to the Gustatory Cortex

Perception of Flavor Depends on Gustatory, Olfactory, and Somatosensory Inputs

Insect Taste Organs Are Distributed Widely on the Body

An Overall View

HROUGH THE SENSES OF SMELL and taste we are able to perceive a staggering number and variety of chemicals in the external world. These chemical senses inform us about the availability of foods and their potential pleasure or danger. Smell and taste also initiate physiological changes required for the digestion and utilization of food. In many animals the olfactory system also serves an important social function by detecting pheromones that elicit innate behavioral or physiological responses.

Although the discriminatory ability of humans is somewhat limited compared with that of many other animals, odor chemists estimate that the human olfactory system may be capable of detecting more than 10,000 different volatile chemicals. Perfumers who are highly trained to discriminate odorants can distinguish as many as 5,000 different types of odorants, and wine tasters can discern more than 100 different components of taste based on combinations of flavor and aroma.

In this chapter we consider how odor and taste stimuli are detected and how they are encoded in patterns of neural signals transmitted to the brain. In recent years much has been learned about the mechanisms underlying chemosensation in a variety of animal species. Certain features of chemosensation have been conserved through evolution, whereas others are specialized adaptations of individual species.

A Large Number of Olfactory Receptor Proteins Initiate the Sense of Smell

Odorants—volatile chemicals that are perceived as odors—are detected by olfactory sensory neurons in

the nose. The sensory neurons are embedded in a specialized olfactory epithelium that lines part of nasal cavity, approximately 5 cm² in area in humans (Figure 32–1), and are interspersed with glia-like supporting cells (Figure 32–2). They are relatively short-lived, with a life span of only 30 to 60 days, and are continuously replaced from a layer of basal stem cells in the epithelium.

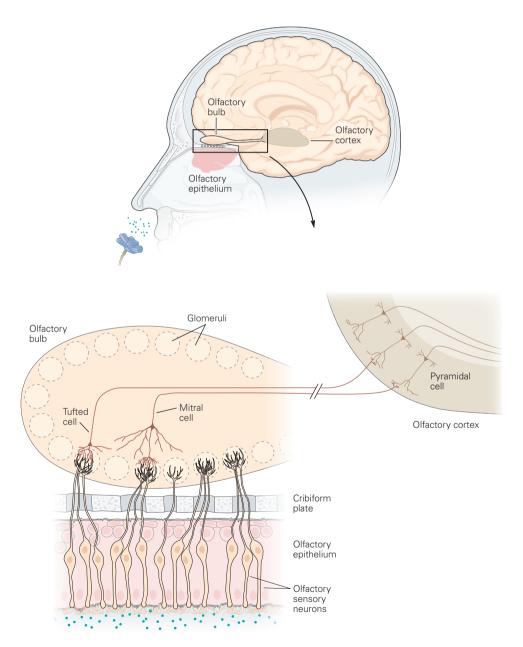

Figure 32–1 The olfactory system. Odorants are detected by olfactory sensory neurons in the olfactory epithelium, which lines part of the nasal cavity. The axons of these neurons project to the olfactory bulb where they terminate on mitral

and tufted cell relay neurons within glomeruli. The relay neuron axons project to the olfactory cortex where they terminate on the dendrites of pyramidal neurons whose axons project to other brain areas.

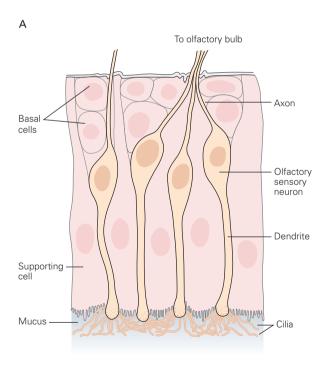

The olfactory sensory neuron is a bipolar nerve cell. A single dendrite extends from the apical end to the epithelial surface, where it gives rise to numerous thin cilia that protrude into the mucus that coats the nasal cavity (Figure 32–2). The cilia have receptors that recognize odorants as well as the transduction machinery needed to amplify the sensory signals and transform them into electrical signals in the neuron's axon, which projects from the basal pole of the neuron to the brain. The axons of olfactory sensory neurons pass through the cribriform plate, a perforated region in the skull above the nasal cavity. The axons then synapse in the olfactory bulb, the first relay in the olfactory pathway (see Figure 32–1).

Mammals Share a Large Family of Odorant Receptors

Odorant receptors are proteins encoded by a multigene family that is evolutionarily conserved and found in all

vertebrate species. Humans have approximately 350 different odorant receptors, whereas mice have approximately 1,000. Although odorant receptors belong to the G protein-coupled receptor superfamily, they share sequence motifs not seen in other superfamily members. Significantly, the odorant receptors vary considerably in amino acid sequence (Figure 32–3A).

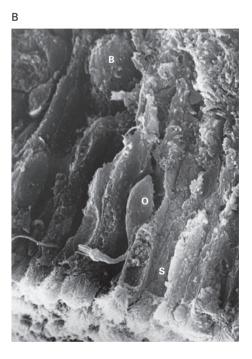

Like other G protein-coupled receptors, odorant receptors have seven hydrophobic regions that are likely to serve as transmembrane domains (Figure 32–3A). Detailed studies of other G protein-coupled receptors, such as the β -adrenergic receptor, suggest that odorant binding occurs in a pocket in the transmembrane region formed by a combination of the transmembrane domains. The amino acid sequences of odorant receptors are especially variable in several transmembrane domains, providing a possible basis for variability in the odorant binding pocket that could account for the ability of different receptors to recognize structurally diverse ligands.

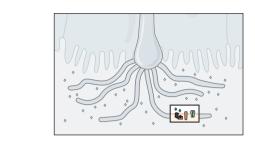

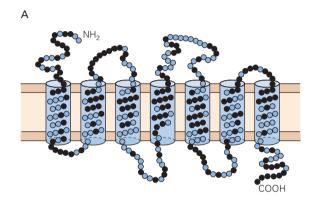

A. The olfactory epithelium contains sensory neurons interspersed with supporting cells as well as a basal layer of stem cells. Cilia extend from the dendrite of each neuron into the mucus lining the nasal cavity. An axon extends from the basal end of each neuron to the olfactory bulb.

B. A scanning electron micrograph of the olfactory epithelium shows the dense mat of sensory cilia at the epithelial

surface. Supporting cells (S) are columnar cells that extend the ful depth of the epithelium and have apical microvilli. Interspersed among the supporting cells are an olfactory sensory neuron (O) with its dendrite and cilia and a basal stem cell (B). (Reproduced, with permission, from Morrison and Costanzo 1990.)

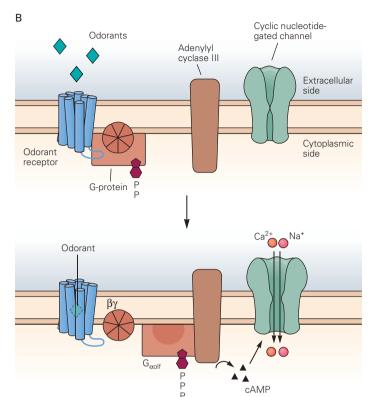

Figure 32-3 Odorant receptors.

A. Odorant receptors have the seven transmembrane domains characteristic of G protein-coupled receptors. They are related to one another but vary in amino acid sequence (positions of highest variability are shown here as black balls). Humans have approximately 350 different odorant receptors, and mice have approximately 1,000. (Reproduced, with permission, from Buck and Axel 1991.)

B. Binding of an odorant causes the odorant receptor to interact with $G_{\alpha olf}$, the α -subunit of a heterotrimeric G protein. This causes the release of a GTP-coupled $G_{\alpha olf}$, which stimulates adenylyl cyclase III, leading to an increase in cAMP. The elevated cAMP in turn induces the opening of cyclic nucleotide-gated cation channels, causing cation influx and a change in membrane potential in the ciliary membrane. (cAMP, cyclic adenosine monophosphate; GTP, quanosine triphosphate.)

A second, smaller family of chemosensory receptors is also expressed in the olfactory epithelium. These receptors, called trace amine-associated receptors (TAARs), are G protein-coupled, but their protein sequence is unrelated to that of odorant receptors. They are encoded by a small family of genes present in humans and mice as well as fish. Studies in mice, which have 14 different olfactory TAARs, indicate that TAARs recognize volatile amines, some of which are enriched in the urine of males compared to that of females. It is possible that this small receptor family has a function distinct from that of the other odorant receptors, perhaps one associated with the detection of social cues.

The binding of an odorant to its receptor induces a cascade of intracellular signaling events that depolarize the olfactory sensory neuron (Figure 32–3B). The depolarization spreads passively to the cell body of the

olfactory sensory neuron, causing action potentials that are actively conducted in the axon to the olfactory bulb.

Humans and other animals rapidly accommodate to odors, as witnessed by the weakening of an unpleasant odor when it is continuously present. The ability to sense an odorant rapidly recovers when the odorant is temporarily removed. The adaptation to odorants is caused in part by modulation of the cyclic nucleotidegated ion channel, but the mechanism by which sensitivity is speedily restored is not yet understood.

Different Combinations of Receptors Encode Different Odorants

To be distinguished perceptually, different odorants must cause different signals to be transmitted from the nose to the brain. This is accomplished in two ways.

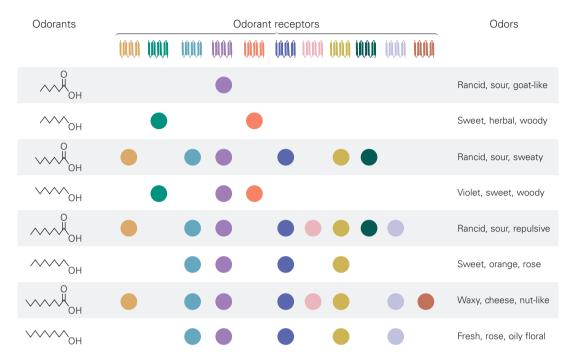

Figure 32–4 Each odorant is recognized by a unique combination of receptors. A single odorant receptor can recognize multiple odorants, and one odorant is recognized by a specific combination of different receptors. That is, different odorants are detected by different combinations of receptors. This combinatorial coding of specific odorants explains how mammals can distinguish odorants with similar chemical structures. The

data in the figure were obtained by testing mouse olfactory sensory neurons with different odorants and then determining the odorant receptor gene expressed by each responsive neuron. The perceived qualities of these odorants in humans are shown on the right. (Adapted, with permission, from Malnic et al. 1999.)

First, each olfactory sensory neuron expresses only one odorant receptor gene and therefore one type of receptor. Second, each receptor recognizes multiple odorants, and conversely each odorant is detected by different types of receptors. Importantly, however, each odorant is detected by a unique constellation of receptors and thus causes a distinctive pattern of signals to be transmitted to the brain.

The combinatorial coding of odorants greatly expands the discriminatory power of the olfactory system. If each odorant were detected by only three different receptors, this strategy could in theory generate millions of different receptor combinations—and an equivalently vast number of different signaling patterns. Interestingly, even odorants with nearly identical structures are recognized by different combinations of receptors (Figure 32–4). The fact that highly related odorants have different receptor codes explains why a slight change in the structure of an odorant can alter its perceived odor. In some cases the result is dramatic, for example changing the perception of a chemical from rose to sour.

A change in concentration of an odorant can also change the perceived odor. For example, a low concentration of thio terpineol smells like tropical fruit, a higher concentration smells like grapefruit, and an even higher concentration smells putrid. As the concentration of an odorant is increased, additional receptors with lower affinity for the odorant are recruited into the response and change the receptor code, providing an explanation for the effects of odorant concentration on perception.

Olfactory Information Is Transformed Along the Pathway to the Brain

Odorants Are Encoded in the Nose by Dispersed Neurons

How is a large array of different odorant receptors organized to generate diverse odor perceptions? This question has been investigated in the mouse. Studies in mice have revealed that olfactory information undergoes a series of spatial transformations as it travels from the olfactory epithelium to the olfactory bulb and then to the olfactory cortex.

Different types of odorant receptors are expressed in several coarse zones of the olfactory epithelium of the mouse (Figure 32–5). Each receptor type is expressed in approximately 5,000 neurons that are confined to one zone. (Recall that each neuron expresses only one odorant receptor gene.) Neurons with the same receptor are randomly scattered within the zone so that neurons with different receptors are interspersed. Although one zone may have more receptors for a particular odorant compared to other zones, all zones contain a variety of receptors, so that a specific odorant may be recognized by receptors in several different zones. The evolutionary significance of the zones is unclear, but, as we shall see, the fact that neurons within different epithelial zones project axons to distinct parts of the olfactory bulb suggests that the arrangement of receptors into discrete zones contributes to the establishment of precise information pathways.

Because each odorant is detected by an ensemble of neurons that is widely dispersed across the epithelial sheet, some receptors detecting a particular odorant will remain functional when part of the epithelium is damaged by respiratory infection.

Sensory Inputs in the Olfactory Bulb Are Arranged by Receptor Type

The axons of olfactory sensory neurons project to the ipsilateral olfactory bulb, whose rostral end lies just above the olfactory epithelium. The sensory axons terminate on the dendrites of olfactory bulb neurons within bundles of neuropil called glomeruli that are arrayed over the bulb's surface (Figure 32–6). In each glomerulus the sensory axons make synaptic connections with three types of neurons: mitral and tufted relay neurons, which project axons to the olfactory cortex, and periglomerular interneurons, which encircle the glomerulus.

The axon of an olfactory sensory neuron terminates in only one glomerulus. Similarly, the primary dendrite of each mitral and tufted relay neuron is confined to a single glomerulus. In each glomerulus the axons of several thousand sensory neurons converge on the dendrites of approximately 40 to 50 relay neurons. This convergence results in approximately a 100-fold decrease in the number of neurons transmitting olfactory signals.

The organization of sensory information in the olfactory bulb is dramatically different from that of the epithelium. Whereas olfactory sensory neurons with the same odorant receptor are randomly

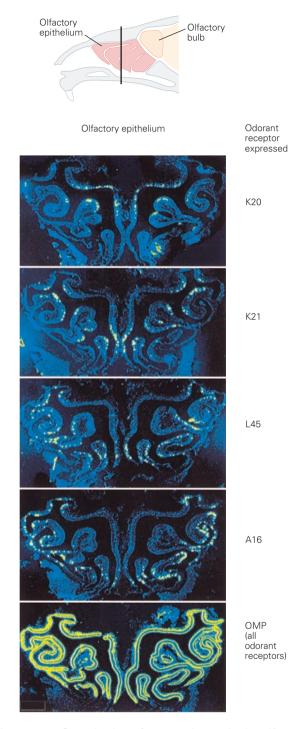

Figure 32–5 Organization of sensory inputs in the olfactory epithelium. Sensory neurons in the olfactory epithelium are distributed in discrete areas known as zones, and each odorant receptor gene is expressed by a small subset of neurons within a single zone. Neurons labeled by four different receptor probes are shown here in different zones in sections through the mouse nose. An olfactory marker protein (OMP) probe labels all neurons expressing odorant receptors. (Adapted, with permission, from Ressler, Sullivan, and Buck 1993; adapted, with permission, from Sullivan et al. 1996.)

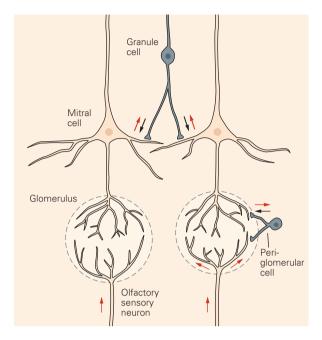

Figure 32–6 Olfactory bulb interneurons. Within the glomerulus, the dendrites of GABAergic periglomerular cells receive excitatory input from olfactory sensory neurons and have reciprocal synapses with the primary dendrites of mitral and tufted relay neurons, suggesting a possible role in signal modification. The dendrites of GABAergic granule cells deeper in the bulb have reciprocal excitatory-inhibitory synapses with the secondary dendrites of the relay neurons and are thought to provide negative feedback to relay neurons that shapes the odor response. (Adapted, with permission, from Shepherd and Greer 1998.)

scattered in one epithelial zone, their axons converge in a few glomeruli at two spots, one on either side of the olfactory bulb (Figure 32–7). Each glomerulus, and each mitral and tufted relay neuron connected to it, receives input from just one type of odorant receptor. The result is a precise arrangement of inputs from different odorant receptors, which is similar between individuals.

Because each odorant is recognized by a unique combination of receptor types, each odorant also activates a particular combination of glomeruli in the olfactory bulb (Figure 32–7B). At the same time, just as an odorant receptor recognizes multiple odorants, a single glomerulus—or a given mitral or tufted cell—is activated by more than one odorant. Closely related odorants can stimulate glomeruli in the same subregion of the bulb, suggesting that the organization of inputs is related to odorant structure. Owing to the nearly stereotyped pattern of receptor inputs in the

olfactory bulb, the patterns of glomerular activation elicited by individual odorants are similar in all individuals and are bilaterally symmetrical in the two adjacent bulbs.

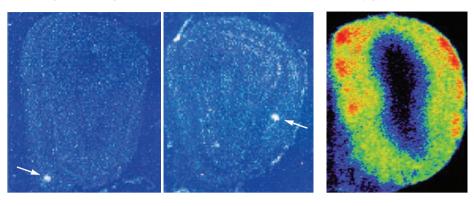

This organization of sensory information in the olfactory bulb is likely to be advantageous in two respects. First, the fact that signals from thousands of sensory neurons with the same odorant receptor type always converge on the same few glomeruli and relay neurons in the olfactory bulb may optimize the detection of odorants present at low concentrations. Second, although olfactory sensory neurons with the same receptor type are dispersed and are continually replaced, the arrangement of inputs in the olfactory bulb remains unaltered. As a result, the neural code for an odorant in the brain is maintained over time, assuring that an odorant encountered previously can be recognized years later.

One mystery that remains unsolved is how all the axons of olfactory sensory neurons with the same type of receptor are directed to the same glomeruli. Studies using transgenic mice indicate that the odorant receptor itself somehow determines the target of the axon, but how it does so is unclear.

Sensory information is processed and possibly refined in the olfactory bulb before it is forwarded to the olfactory cortex. Each glomerulus is encircled by periglomerular interneurons that receive excitatory input from sensory axons and form inhibitory dendrodendritic synapses with mitral and tufted cell dendrites in that glomerulus and perhaps adjacent glomeruli. The periglomerular interneurons may therefore have a role in signal modulation. In addition, granule cell interneurons deep in the bulb provide negative feedback onto mitral and tufted cells. The granule cell interneurons are excited by the basal dendrites of mitral and tufted cells and in turn inhibit those postsynaptic relay neurons and others with which they are connected. The lateral inhibition afforded by these connections is thought to dampen signals from glomeruli and relay neurons that respond to an odorant only weakly, thereby sharpening the contrast between important and irrelevant sensory information before its transmission to the cortex.

Other potential sources of signal refinement are the retrograde projections to the olfactory bulb from the olfactory cortex, basal forebrain (horizontal limb of the diagonal band), and midbrain (locus ceruleus and raphe nuclei). These connections may modulate olfactory bulb output according to the physiological state of an animal. When the animal is hungry, for example, some centrifugal projections might heighten the perception of the aroma of foods. A Axons of neurons with the same odorant receptor converge on a few glomeruli

B One odorant can activate many glomeruli

C The olfactory bulb has a precise map of odorant receptor inputs

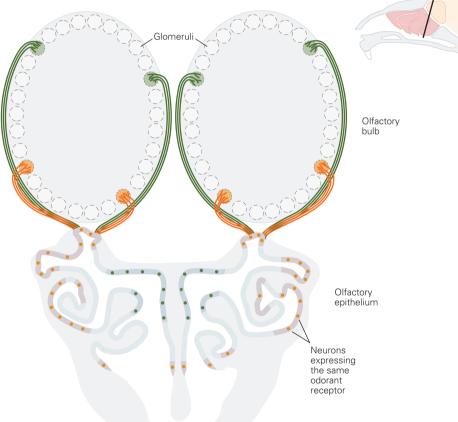

Figure 32-7 Odor responses in the olfactory bulb.

A. The axons from neurons in one epithelial zone with the same odorant receptor type usually converge to two glomeruli, one on each side of the olfactory bulb. Here a probe specific for one odorant receptor gene labeled a glomerulus on the medial side (left) and lateral side (right) of a mouse olfactory bulb. The probe hybridized to receptor messenger RNAs present in sensory axons in these coronal sections. (Adapted from Ressler, Sullivan, and Buck 1994.)

B. This section of a rat olfactory bulb shows the uptake of radiolabeled 2-deoxglucose at multiple foci (red) following

exposure of the animal to the odorant methyl benzoate. The labeled foci correspond to numerous glomeruli at different locations in the olfactory bulb. (Reproduced, with permission, from Johnson, Farahbod, and Leon 2005.)

C. The olfactory bulb has a precise map of odorant receptor inputs because each glomerulus is dedicated to only one type of receptor. The maps in the two olfactory bulbs are bilaterally symmetrical and are nearly identical across individuals. The maps on the medial and lateral sides of each bulb are similar, but slightly displaced along the dorsal-ventral and anteriorposterior axes.

The Olfactory Bulb Transmits Information to the Olfactory Cortex

The axons of the mitral and tufted relay neurons of the olfactory bulb project through the lateral olfactory tract to the olfactory cortex (Figure 32–8 and see Figure 32–1). The olfactory cortex, defined roughly as that portion of the cortex that receives a direct projection from the olfactory bulb, comprises five main areas: (1) the anterior olfactory nucleus, which connects the two olfactory bulbs through a portion of the anterior commissure; (2) the anterior and posterior cortical nuclei of the amygdala; (3) the olfactory tubercle; (4) part of the entorhinal cortex; and (5) the piriform cortex, the largest and considered the major olfactory cortical area.

In the piriform cortex the axons of olfactory bulb mitral and tufted cells leave the lateral olfactory tract to form excitatory glutamatergic synapses with pyramidal neurons, the projection neurons of the cortex. Signal transmission by the pyramidal neurons appears to be modulated by inhibitory inputs from local GABA-ergic interneurons as well as by excitatory inputs from neighboring pyramidal neurons and the piriform cortex of the other hemisphere. The piriform cortex also receives centrifugal inputs from modulatory brain areas, suggesting that its activity may be adjusted according to behavioral state. Finally, the olfactory cortex projects to the olfactory bulb, providing yet another possible means of signal modulation.

As with the olfactory bulb relay neurons, individual pyramidal neurons can be activated by more than one odorant. However, the pyramidal neurons activated by a particular odorant are scattered across the piriform cortex, an arrangement different from that of the olfactory bulb. Mitral cells in different parts of the olfactory bulb can project axons to the same subregion of the piriform cortex, further indicating that the highly organized map of odorant receptor inputs in the olfactory bulb is not recapitulated in the cortex.

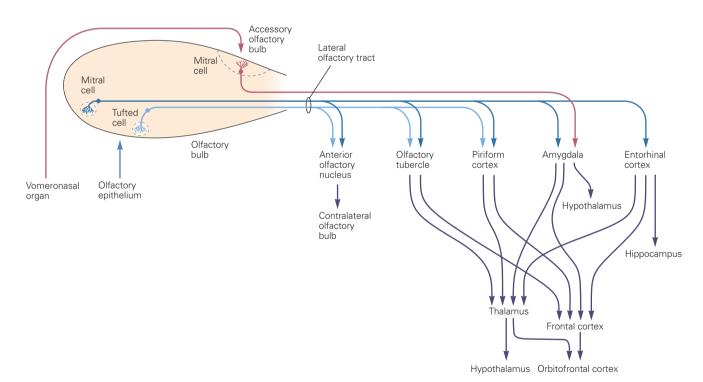

Figure 32–8 The olfactory cortex. The axons of mitral and tufted relay neurons of the olfactory bulb project through the lateral olfactory tract to the olfactory cortex. The olfactory cortex consists of a number of distinct areas, the largest of which is the piriform cortex. From these areas olfactory information is transmitted directly to other brain areas as well as indirectly

via the thalamus. Targets include frontal and orbitofrontal areas of the neocortex, which are thought to be important for odor discrimination, and the amygdala and hypothalamus, which may be involved in emotional and physiological responses to odors. Mitral cells in the accessory olfactory bulb project to specific areas of the amygdala that transmit signals to the hypothalamus.

Output from the Olfactory Cortex Reaches Higher Cortical and Limbic Areas

Pyramidal neurons in the olfactory cortex transmit information indirectly to the orbitofrontal cortex through the thalamus and directly to the frontal cortex. These pathways to higher cortical areas are thought to be important in odor discrimination. In fact, people with lesions of the orbitofrontal cortex are unable to discriminate odors. Interestingly, recordings in the orbitofrontal cortex suggest that some individual neurons in that area receive multimodal input and can respond, for example, to the smell, sight, and taste of a banana.

Most areas of the olfactory cortex also relay information to the lateral hypothalamus, an area important in appetite. In addition, studies of rodents indicate that one part of the olfactory cortex, the anterior cortical nucleus of the amygdala, transmits information to other areas of the amygdala and to more anterior regions of the hypothalamus, including those involved in reproduction. These limbic areas are thought to mediate the emotional and motivational aspects of smell as well as many of the behavioral and physiological effects of odorants. In animals they may be important in the generation of stereotyped behavioral and physiological responses to odors of predators or to pheromones that are detected in the olfactory epithelium.

Olfactory Acuity Varies in Humans

Olfactory acuity can vary as much as 1,000-fold among humans, even among people with no obvious abnormality. The most common olfactory aberration is *specific anosmia*. An individual with a specific anosmia has lowered sensitivity to a specific odorant even though sensitivity to other odorants appears normal. Specific anosmias to some odorants are common, a few occurring in 1 to 20% of people. For example, 12% of individuals tested in one study exhibited a specific anosmia for musk. Recent studies indicate that specific anosmias can be caused by mutations in particular odorant receptors.

Far rarer abnormalities of olfaction, such as *general anosmia* (complete lack of olfactory sensation) or *hyposmia* (diminished sense of smell), are often transient and can derive from respiratory infections. Chronic anosmia or hyposmia can result from damage to the olfactory epithelium caused by infections; from particular diseases, such as Parkinson disease; or from head trauma that severs the olfactory nerves passing through holes in the cribriform plate, which

then become blocked by scar tissue. Olfactory hallucinations of repugnant smells (*cacosmia*) can occur as a consequence of epileptic seizures.

Odors Elicit Characteristic Innate Behaviors

Pheromones Are Detected in Two Olfactory Structures

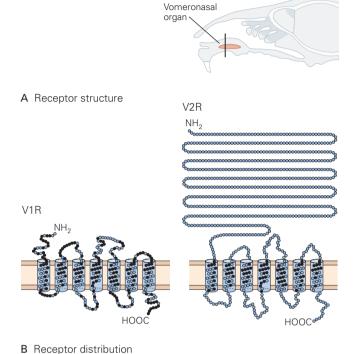

In many animals the olfactory system detects not only odors but also pheromones, chemicals that are released from animals and influence the behavior or physiology of members of the same species. Pheromones play important roles in a variety of mammals, although they have not been compellingly demonstrated in humans. Often contained in urine or glandular secretions, some pheromones modulate the levels of reproductive hormones or stimulate sexual behavior or aggression. Pheromones are detected by two separate structures: the nasal olfactory epithelium, where odorants are detected, and the vomeronasal organ, an accessory olfactory organ thought to be specialized for pheromone detection.

The vomeronasal organ is present in many mammals although not in humans. It is a tubular structure in the nasal septum that has a duct opening into the nasal cavity and one inner wall lined by a sensory epithelium (Figure 32–9). Signals generated by sensory neurons in the epithelium of the vomeronasal organ follow a distinct pathway. They travel through the accessory olfactory bulb to the medial amygdala and from there to the hypothalamus, which controls a variety of physiological and behavioral responses.

Sensory detection in the vomeronasal organ differs from that in the olfactory epithelium. The vomeronasal organ has two different families of chemosensory receptors, the V1R and V2R families. In the mouse each family has more than one hundred members. Variation in amino acid sequence between members of each receptor family suggests that each family may recognize a variety of different ligands. Like odorant receptors, V1R and V2R receptors have the seven transmembrane domains typical of G protein-coupled receptors. The V2R receptor differs from both V1R and odorant receptors in having a large extracellular domain at the N-terminal end (Figure 32–9A). By analogy with receptors with similar structures, ligands may bind V1Rs in a membrane pocket formed by a combination of transmembrane domains, whereas binding of V2Rs may occur in the large extracellular domain.

The V1R and V2R families are each localized in one of two zones in the vomeronasal organ that express

V1R

V2R

different G proteins (Figure 32–9B and C). The V1R and V2R genes are each expressed in a small percentage of neurons scattered throughout one zone, an arrangement similar to that of odorant receptors in the olfactory epithelium. Similar to the main olfactory bulb, the vomeronasal neurons with the same receptor type project to the same glomeruli in the accessory olfactory bulb, although the glomeruli for each receptor type are more numerous and their distribution less stereotyped than in the main olfactory bulb.

Invertebrate Olfactory Systems Can Be Used to Study Odor Coding and Behavior

Because invertebrates have simple nervous systems and often respond to olfactory stimuli with stereotyped behaviors, they are useful for understanding the relationship between the neural representation of odor and behavior.

Certain features of chemosensory systems are highly conserved in evolution. First, all metazoan animals can detect a variety of organic molecules using specialized chemosensory neurons with cilia or microvilli that contact the external environment. Second, the initial events of odor detection are mediated by families of transmembrane receptors with specific expression patterns in peripheral sensory neurons. Other features of the olfactory system differ between species, reflecting selection pressures and evolutionary histories of the animals.

The Anatomy of the Insect Olfactory System Resembles That of Vertebrates

The primary sensory organs of insects are the antennae and appendages known as maxillary palps near the mouth (Figure 32–10A). Whereas mammals have

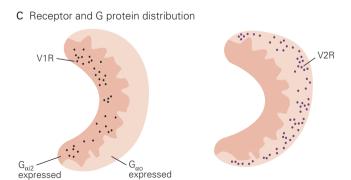

Figure 32–9 Candidate pheromone receptors in the vomeronasal organ.

A. The V1R and V2R families of receptors are expressed in the vomeronasal organ. In the mouse each family has more than 100 members, which vary in protein sequence. Members of both families have the seven transmembrane domains of G protein-coupled receptors, but V2R receptors also have a large extracellular domain at the N-terminal end that may be the site of ligand binding.

millions of olfactory neurons, insects have a much smaller number. There are approximately 2,600 olfactory neurons in the simple fruit fly *Drosophila* and approximately 60,000 in a complex insect, the honeybee.

The insect odorant receptors were discovered by finding multigene receptor families in the *Drosophila* genome, and these genes have now been examined in other insect genomes as well. Remarkably, they have little similarity to mammalian odorant receptors save

for the presence of many transmembrane domains. Indeed, insect receptors appear to have an independent evolutionary origin from mammalian receptors, and may not even be G protein-coupled receptors—an extreme example of the fast evolutionary change observed across all olfactory receptor systems. In *Drosophila* the main odorant receptor family has only 60 genes rather than the hundreds characteristic of vertebrates. The malaria mosquito *Anopheles gambiae* and the honeybee have similar numbers (85–95 genes), suggesting that there is little variety in the receptor families of insects.

Despite the molecular dissimilarity in receptors, the anatomical organization of the fly's olfactory system is quite similar to that of vertebrates. Each olfactory neuron expresses one or sometimes two functional odorant receptor genes. The neurons expressing a particular gene are loosely localized to a region of the antenna, but interspersed with neurons expressing other genes (Figure 32–10B). This scattered distribution is not the case at the next level of organization, the antennal lobe. Axons from sensory neurons that express one type of receptor converge on two invariant glomeruli in the antennal lobe, one each on the left and right sides of the animal (Figure 32–10C). This organization is strikingly similar to that of the first sensory relay in the vertebrate olfactory bulb and is found in the moth, honeybee, and other insects.

Because there are only a few dozen receptor genes in insects, it is possible to characterize the entire repertory of odorant-receptor interactions, a goal that is not yet attainable in mammals. Sophisticated genetic methods can be used to label and record from a *Drosophila* neuron expressing a single known odorant receptor gene. By repeating this experiment with many receptors and odors, the receptive fields of the odorant receptors have been defined, and shown to be quite diverse.

In insects individual odorant receptors can detect large numbers of odorants, including odorants with very different chemical structures. This broad recognition of odorants by "generalist" receptors is necessary if only a small number of receptors is available to detect all biologically significant odorants. A single insect receptor protein that detects many odors can be stimulated by some odors and inhibited by others, often with distinct temporal patterns. A subset of insect odorant receptors is more selective in its recognition, and conveys information about pheromones or other unusual odors like carbon dioxide. Thus the coding potential of each olfactory neuron can be broad or narrow, and arises from a combination of stimulatory and inhibitory signals delivered to its receptors.

Information from the olfactory neurons is relayed to the first processing station, the antennal lobe

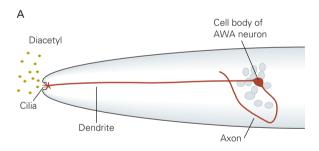

(Figure 32–10A). Sensory neurons expressing the same odorant receptor converge onto a small number of projection neurons in one glomerulus of the antennal lobe. Because Drosophila glomeruli are stereotyped in position and have one type of odorant receptor input, the transformation of information across the synapse can be described. Convergence leads to a great increase in signal-to-noise ratios of olfactory signals, so projection neurons are much more sensitive to odor than individual olfactory neurons. Within the antennal lobe most information from an individual olfactory neuron goes to one glomerulus, but information is also distributed across the entire antennal lobe and processed by excitatory and inhibitory interneurons that connect many glomeruli. Excitatory interneurons distribute signals to projection neurons at distal locations, and inhibitory interneurons feed back onto the olfactory sensory neurons to dampen their input.

The projection neurons from the antennal lobe extend to higher brain centers called mushroom bodies and lateral protocerebrum (Figure 32–10A). These structures may represent insect equivalents of the olfactory cortex. The mushroom bodies are sites of olfactory associative learning and multimodal associative learning; the lateral protocerebrum is important for innate olfactory avoidance responses. At this stage projection neurons form complex connections with a large number of downstream neurons. Neurons in higher brain centers in Drosophila have the potential to integrate information from many receptors. Because they respond to only a small number of odors, their tuning to odors appears to be far more specific than that of the sensory neurons or antennal projection neurons. Even this higher-order pattern in the lateral protocerebrum seems highly reproducible from fly to fly, suggesting that a detailed higher-order map of insect odor representation can be defined.

Olfactory Cues Elicit Stereotyped Behaviors and Physiological Responses in the Nematode

The nematode roundworm *Caenorhabditis elegans* has one of the simplest nervous systems in the animal kingdom, with only 302 neurons in the entire animal. Of these, 32 are ciliated chemosensory neurons. Because *C. elegans* has strong behavioral responses to a wide variety of chemicals it has been a useful animal for relating olfactory signals to behavior. Each chemosensory neuron detects a specific set of chemicals and activation of the neuron is required for the behavioral responses to those substances. The neuron for a particular response, such as attraction to a specific odor, occurs in the same position in all individuals.

The molecular mechanisms of olfaction in C. elegans were elucidated through genetic screens for anosmic worm mutants. The G protein-coupled receptor for the volatile odorant diacetyl emerged from these screens (Figure 32–11). This receptor is one of approximately 1,700 predicted G protein-coupled chemoreceptor genes in C. elegans, the largest number of chemoreceptors among known genomes. Other kinds of chemosensory receptors are also present; for example, C. elegans senses external oxygen levels indirectly by detecting soluble guanylate cyclases that bind directly to oxygen. With so many chemoreceptors, nematodes are able to recognize a large variety of odors with great sensitivity. Downstream of the receptors some chemosensory neurons use G proteins to regulate cyclic guanosine 3'-5' monophosphate (cGMP) and a cGMP-gated channel, a signal transduction pathway like that of vertebrate photoreceptors. Other chemosensory neurons signal through a transient receptor potential vanilloid (TRPV) channel, like vertebrate nociceptive neurons.

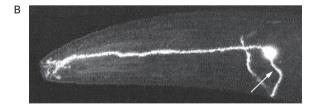

Figure 32–11 The receptor for diacetyl is expressed in a specific chemosensory neuron in the nematode worm *C. elegans*.

A. A lateral view of the worm's anterior end shows the cell body and processes of the AWA chemosensory neuron. The dendritic process terminates in cilia that are exposed to environmental chemicals. The neuron detects the volatile chemical diacetyl; animals with a mutation in the *odr-10* gene are unable to sense diacetyl.

B. The *odr-10* gene product, marked with a fusion to a fluorescent reporter protein, is seen only in the AWA neuron, whose axon is marked with an arrow. (Reproduced, with permission, from Sarafi-Reinach and Sengupta 2000.)

The "one neuron, one receptor" principle observed in vertebrates and insects does not operate in nematodes as the number of neurons is much smaller than the number of receptors. Each of the many chemoreceptor genes is typically expressed in only one pair of chemosensory neurons, but each neuron expresses many receptor genes. The small size of its nervous system limits the olfactory computations that *C. elegans* can perform. For example, a single neuron responds to many odors, but odors can be distinguished efficiently only if they are sensed by different primary sensory neurons.

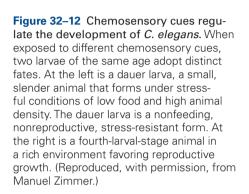

The relationship between odor detection and behavior has been explored in *C. elegans* through genetic manipulations. For example, diacetyl is normally attractive to worms, but when the diacetyl receptor is experimentally expressed in an olfactory neuron that normally senses repellents, the animals are instead repelled by diacetyl. This observation indicates that specific sensory neurons encode the hardwired behavioral responses of attraction or repulsion, and that a "labeled line" connects specific odors to specific behaviors. Similar ideas have emerged from genetic manipulations of taste systems in mice and flies, where sweet and bitter preference pathways appear to be encoded by different sets of sensory cells.

Olfactory cues are linked to physiological responses as well as behavioral responses in nematodes. Food and pheromone cues that regulate development are detected by specific sensory neurons through G protein-coupled receptors. At low pheromone and high food levels animals rapidly develop to adulthood, whereas high pheromone levels and scarce food drive entry into a long-lived arrested larval stage called a *dauer larva* (Figure 32–12). Activation of these sensory neurons ultimately regulates the activity of an insulin signaling pathway that controls physiology and growth, as well as life span, of the nematode. It is an open question whether the chemosensory systems and physiological systems of other animals are as entangled as they are in nematodes.

Strategies for Olfaction Have Evolved Rapidly

Why have independent families of odorant receptors evolved in mammals, nematodes, and insects? And why have the families changed so rapidly compared to genes involved in other important biological processes? The answer lies in a fundamental difference between olfaction and other senses such as vision, touch, and hearing.

Most senses are designed to detect physical entities with reliable physical properties: photons, pressure, or sound waves. By contrast, olfactory systems are designed

to detect organic molecules that are infinitely variable and do not fit into a simple continuum of properties. Moreover, the organic molecules that are detected are produced by other living organisms, which evolve far more rapidly than the world of light, pressure, and sound.

An ancient olfactory system was present in the common ancestors of all animals that exist today. That ancestor lived in the ocean, where it gave rise to different lineages for mammals, insects, and nematodes. Those three phyla of animals came onto land hundreds of millions of years after the phyla diverged. Each phylum independently modified its olfactory system to detect airborne odors, leading to diversification of the receptors.

A consideration of the natural history of dipteran and hymenopteran insects, which have evolved in the last 200 million years, helps explain the rapid diversification of the odorant receptors. These insects include honeybees that pollinate flowers, fruit flies that feed on rotting fruit, flesh flies that arrive within minutes

of death, and mosquitoes that seek animal prey. The odorants that are important for the survival of these insects are radically different, and receptor genes that are tuned to those odorants have evolved accordingly.

The Gustatory System Controls the Sense of Taste

Taste Has Five Submodalities or Qualities

The primary function of the gustatory system is nutritional. Humans and other mammals can distinguish five different taste qualities: sweet, bitter, salty, sour, and umami, the taste associated with amino acids. Taste chemicals (tastants) perceived as sweet are associated with food high in caloric content, while those sensed as umami are indicative of protein.

Consistent with the nutritional importance of carbohydrates and proteins, both sweet and umami

tastants elicit pleasurable sensations in humans and are attractants for animals. In contrast, bitter tastants, which are often found in poisonous plants, elicit an aversive response that is innate in animals as well as human infants and likely prevents the ingestion of toxic substances.

Taste is often thought to be synonymous with flavor. However, taste refers strictly to the five qualities encoded in the gustatory system, whereas flavor, with its rich and varied qualities, actually stems from a combination of inputs from the gustatory, olfactory, and somatosensory systems.

Taste Detection Occurs in Taste Buds

In the gustatory system sensory signals generated in the mouth are relayed through the brain stem and thalamus to the gustatory cortex (Figure 32–13). Tastants are detected by taste receptor cells that are clustered in taste buds. Although the majority of taste buds in humans are located on the tongue, some can also be found on the palate, pharynx, epiglottis, and upper third of the esophagus.

Taste buds on the tongue occur in structures called papillae, of which there are three types based on morphology and location. *Fungiform papillae*, located on the anterior two-thirds of the tongue, are peg-like structures that are topped with taste buds. Both the *foliate papillae*, situated on the posterior edge of the tongue, and the *circumvallate papillae*, of which there are only a few in the posterior area of the tongue, are structures surrounded by grooves lined with taste buds (Figure 32–14A). Each fungiform papilla contains one to five taste buds, while each circumvallate or foliate papilla contains hundreds.

The taste bud is a garlic-shaped structure embedded in the epithelium. A small opening at the epithelial

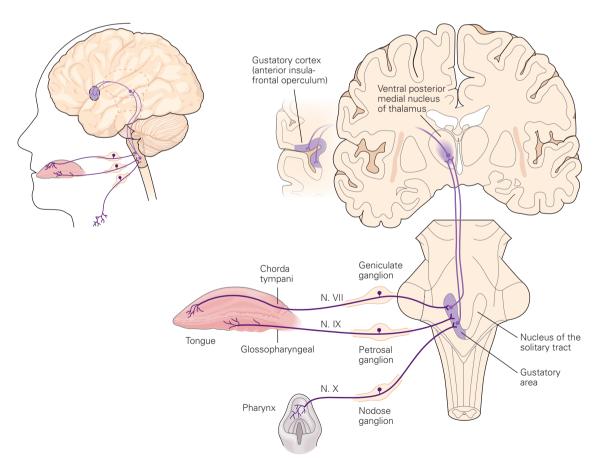

Figure 32–13 The gustatory system. Tastants are detected in taste buds in the oral cavity. Taste buds on the tongue are innervated by the peripheral fibers of gustatory sensory neurons, which travel in the glossopharyngeal and chorda tympani

nerves and terminate in the nucleus of the solitary tract in the brain stem. From there taste information is relayed through the thalamus to the gustatory cortex as well as to the hypothalamus. surface, the taste pore, is the point of contact with tastants (Figure 32–14B). Each taste bud contains approximately 100 taste receptor cells (taste cells), elongated cells that stretch from the taste pore to the basal area of the bud. The taste bud also contains other elongated cells that are thought to serve a supporting function, as well as a small number of round cells at the base, which are thought to serve as stem cells. Taste cells are short-lived and appear to be continually replaced from the stem cell population.

Each taste cell extends microvilli into the taste pore, allowing the cell to contact chemicals dissolved in saliva at the epithelial surface. At its basal end the taste cell contacts the afferent fibers of gustatory sensory neurons, whose cell bodies reside in specific sensory ganglia (Figures 32–13 and 32–14). Although taste cells are nonneural, their contacts with the gustatory sensory neurons have the morphological characteristics of chemical synapses, including clustered presynaptic vesicles. Taste cells also resemble neurons in that they are electrically excitable; they have voltage-gated

Na⁺, K⁺, and Ca²⁺ channels and are capable of generating action potentials.

Each Taste Is Detected by a Distinct Sensory Transduction Mechanism and Distinct Population of Taste Cells

Each of the five taste qualities involves a different sensory transduction mechanism in the microvilli of taste cells. There are, however, two general types. Bitter, sweet, and umami tastants interact with G protein-coupled receptors, whereas salty and sour tastants appear to involve specific ion channels (Figure 32–15). These interactions depolarize the taste cell, leading to the generation of action potentials in the afferent gustatory fibers.

Sweet Taste

Compounds that humans perceive as sweet include sugars, artificial sweeteners such as saccharin and

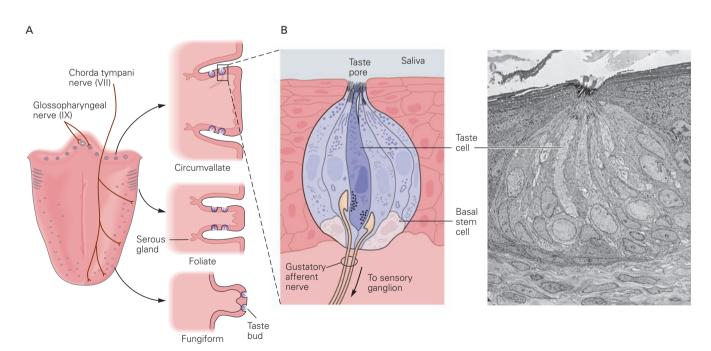

Figure 32–14 Taste buds are clustered in papillae on the tongue.

A. The three types of papillae—circumvallate, foliate, and fungiform—differ in morphology and location on the tongue and are differentially innervated by the chorda tympani and glossopharyngeal nerves.

B. Each taste bud contains 50 to 150 elongated taste receptor cells, as well as supporting cells and a small population of basal

stem cells. The taste cell extends microvilli into the taste pore, allowing it to detect tastants dissolved in saliva. At its basal end the taste cell contacts gustatory sensory neurons that transmit stimulus signals to the brain. The scanning electron micrograph shows a taste bud in a foliate papilla in a rabbit. (Reproduced, with permission, from Royer and Kinnamon 1991.)

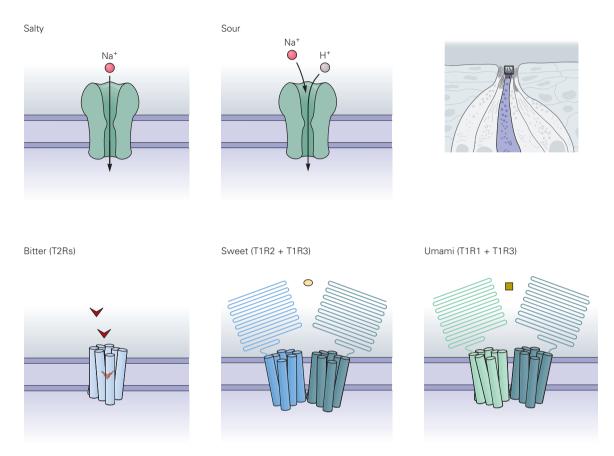

Figure 32–15 Sensory transduction in taste cells. Different taste qualities involve different detection mechanisms in the microvilli at the apical taste pore of taste cells (see Figure 32–14B). Salty and sour tastants activate ion channels, whereas tastants perceived as bitter, sweet, or umami activate G

protein-coupled receptors. Bitter tastants are detected by T2R receptors, whereas sweet tastants are detected by a combination of T1R2 and T1R3 and umami tastants by a combination of T1R1 and T1R3.

aspartame, a few proteins such as monellin and thaumatin, and some p-amino acids. All of these sweet-tasting compounds are detected by a complex of two related G protein-coupled receptors, T1R2 and T1R3 (Figure 32–16).

T1R receptors have a large N-terminal extracellular domain (Figure 32–15) like the V2R receptors of vomeronasal neurons. Changing a single amino acid in this domain in mice can alter an animal's sensitivity to sweet compounds. Indeed, T1R3 was initially discovered by examining genes at the mouse saccharin preference (Sac) locus, a chromosomal region that governs sensitivity to saccharin, sucrose, and other sweet compounds.

In mice, taste cells with T1R2 receptors are found mostly in foliate and circumvallate papillae; almost invariably those cells also possess T1R3 receptors (Figure 32–17A). Gene knockout experiments in mice indicate that the T1R2/T1R3 complex mediates the detection of

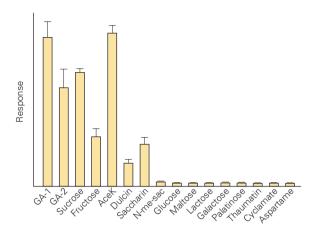

all sweet compounds except for high concentrations of sugars, which can also be detected by T1R3 alone.

Umami Taste

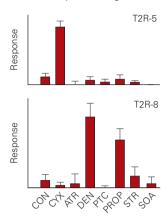

Umami is the name given to the savory taste of monosodium glutamate, an amino acid widely used as a flavor enhancer. It is believed that the pleasurable sensation associated with umami taste encourages the ingestion of proteins and is thus important to nutrition.

The taste cell receptor responsible for umami taste is a complex of two related G protein-coupled receptors: T1R1 and T1R3 (Figure 32–15). In both humans and mice the T1R1/T1R3 complex can interact with all L-amino acids (Figure 32–16B), but in humans it is preferentially activated by glutamate. Purine nucleotides, such as inosine 5'-monophosphate (IMP), are often added to monosodium glutamate to enhance its

A T1R2 + T1R3 recognizes sweet tastants

C T2R receptors recognize bitter tastants

B T1R1 + T1R3 recognizes umami tastants

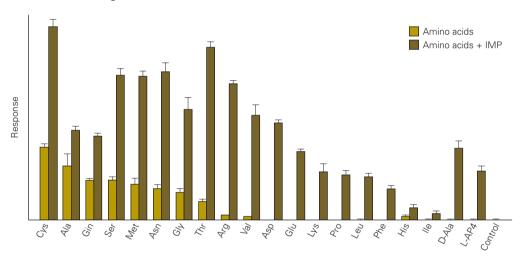

Figure 32–16 Tastants recognized by T1R and T2R receptors. A calcium-sensitive dye was used to test whether T1R and T2R receptors expressed in a tissue culture cell line could detect tastants.

A. Cells expressing both rat T1R2 and rat T1R3 responded to a number of sweet compounds. (Reproduced, with permission, from Nelson et al. 2001.)

B. Cells expressing mouse T1R1 and mouse T1R3 responded to numerous L-amino acids (umami taste). Responses were potentiated by inosine monophosphate (IMP). (Reproduced, with permission, from Nelson et al. 2002.)

C. Cells expressing different T2R receptors responded selectively to different bitter compounds. Cells expressing mouse T2R5 responded most vigorously to cycloheximide (CYX), whereas cells expressing mouse T2R8 responded preferentially to denatonium (DEN) and 6-n-propyl-2-thiouracil (PROP). (ATR, atropine; CON, control; PTC, phenyl thiocarbamide; SOA, sucrose octaacetate; STR, strychnine.) (Reproduced, with permission, from Chandrashekar et al. 2000.)

pleasurable umami taste. Interestingly, in vitro studies show that IMP potentiates the responsiveness of T1R1/T1R3 to L-amino acids, suggesting that IMP acts on the receptor itself (Figure 32–16B).

Taste cells with both T1R1 and T1R3 are concentrated in fungiform papillae (Figure 32–17A). Studies in mice in which individual T1R genes have been deleted

indicate that the T1R1/T1R3 complex is solely responsible for umami taste.

Bitter Taste

Bitter taste is thought to have evolved as a means of preventing ingestion of toxic molecules. Bitter taste sensations are elicited by a variety of compounds, including caffeine, nicotine, alkaloids, and denatonium, the most bitter-tasting compound known.

Bitter tastants are detected by a family of approximately 30 G protein-coupled receptors called T2Rs (see Figure 32–15). These receptors vary in protein sequence, consistent with their ability to recognize bitter compounds with diverse chemical structures. Indeed, different T2R receptors recognize different bitter compounds (Figure 32–16C). A single taste cell can express many, and probably all, types of T2R receptors (Figure 32–17B). This arrangement implies that information about different bitter tastants is integrated in individual taste cells. Because different bitter compounds are detected by the same cells, all these compounds elicit the same perceptual quality: bitter. The degree of bitterness might be caused by a compound's effectiveness in activating bitter taste cells.

Interestingly, genetic differences in the ability to perceive specific bitter compounds have been identified in both humans and mice and mapped to specific chromosomal loci. It was by examining genes at these loci that the T2R receptors for bitter tastants were first identified. In at least some cases the gene responsible for the genetic difference has proved to be a particular T2R gene. Thus, at least some bitter compounds may be recognized primarily or perhaps exclusively by only one of the 30 or so T2R receptor types.

In mice taste cells expressing T2R receptors are found in both foliate and circumvallate papillae (Figure 32–17C). Taste cells express either T2R or T1R receptors,

Figure 32–17 Expression of T1R and T2R receptors on the tongue. Sections of mouse or rat tongue were hybridized to probes that label T1R or T2R mRNAs to detect their sites of expression in taste cells.

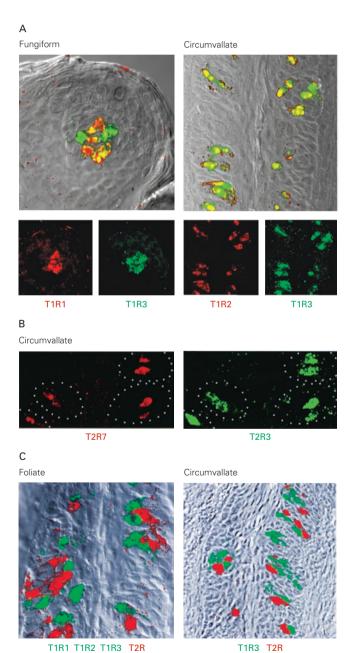

A. T1R3 is expressed in taste cells of all three types of papillae. However, T1R1 is found mostly in fungiform papillae, whereas T1R2 is located predominantly in circumvallate (and foliate) papillae. Overlap between sites of expression appears as yellow cells in the panels at the top. The T1R1-T1R3 umami receptor is more frequently found in fungiform papillae, whereas the T1R2-T1R3 sweet receptor is more frequently found in circumvallate and foliate papillae. (Reproduced, with permission, from Nelson et al. 2001.)

- **B.** A taste cell that detects bitter tastants can express several different T2R receptors. Here probes for T2R3 and T2R7 labeled the same taste cells in circumvallate papillae. (Reproduced, with permission, from Adler et al. 2000.)
- C. T1R and T2R receptors are expressed in different taste cells. Taste cells labeled by a T1R3 probe or mixed T1R probes (green) did not overlap with cells labeled by a mixture of T2R probes (red). (Reproduced, with permission, from Nelson et al. 2001.)

but a single taste bud can contain taste cells of both types. Such mixing of cells accords with the observation that a single taste bud can be activated by more than one class of tastant, for example sweet as well as bitter.

Salty Taste

Salty compounds are essential to animals for the maintenance of electrolyte balance. It is thought that their detection is mediated by specific ion channels, but the

underlying mechanisms are not yet known (see Figure 32–15). Detection of sodium chloride (NaCl), for example, might result from a diffusion of Na⁺ ions down an electrochemical gradient through Na⁺ channels on taste cell microvilli, or it might involve ion channels that are opened by Na⁺ ions.

Sour Taste

Sour taste is associated with acidic food or drink. As with bitter compounds, animals are innately averse to sour substances, prompting the suggestion that the adaptive advantage of sour taste is avoidance of spoiled foods.

The molecular mechanisms underlying sour stimulus transduction in the taste cell have not been identified. Detection of sour tastants may involve ion channels that are opened by H⁺ ions or that allow an influx of those ions that results in a depolarization of the taste cell (Figure 32–15). However, as with salty taste, the proteins responsible for sour taste transduction have not yet been defined.

Molecular-genetic studies indicate that bitter, sweet, and umami tastants are each detected by a distinct subset of taste cells. As already discussed, a combination of T1R1 and T1R3 is responsible for all umami taste, while a combination of T1R2 and T1R3 is needed for all sweet taste detection except for the detection of high concentrations of sugars, which can be mediated by T1R3 alone. T1R1 and T1R2 are expressed by separate subsets of taste cells, indicating that the detection of sweet and umami tastants is segregated.

In mice a transduction protein (PLCb2) is required for detection of bitter, sweet, and umami tastants. When this protein is expressed only in cells with bitter receptors, the cells are responsive to bitter compounds but not to sweet compounds or amino acids. This result confirms that taste cells that detect bitter compounds are distinct from those that detect sweet and umami tastants. Taste cells that detect salty and sour tastants may form two additional subsets of cells.

Studies in mice further indicate that it is the taste cells rather than the receptors that determine the animal's response to a tastant. The human bitter receptor T2R16 recognizes a bitter tastant that mice cannot detect. When this receptor was expressed in mouse taste cells that express the T1R2/T1R3 sweet complex, the human T2R ligand elicited an attractive response; when it was expressed in mouse cells that express T2R bitter receptors, the same ligand instead caused aversion. These findings suggest that innate responses of mice to sweet and bitter compounds result from

specific gustatory pathways (labeled lines) that link the activation of different subsets of taste cells to different behavioral outcomes.

Sensory Neurons Carry Taste Information from the Taste Buds to the Brain

Each taste cell is innervated at its base by the peripheral branches of the axons of primary sensory neurons (Figure 32–14). Each sensory fiber branches many times, innervating several taste cells within numerous taste buds. The release of neurotransmitter from taste cells onto the sensory fibers induces action potentials in the fibers and the transmission of signals to the sensory cell body.

The cell bodies of gustatory sensory neurons lie in the geniculate, petrosal, and nodose ganglia. The peripheral branches of gustatory sensory neurons in these three ganglia travel in cranial nerves VII, IX, and X (Figure 32–13).

The central branches of axons of the gustatory sensory neurons enter the medulla, where they terminate on neurons in the gustatory area of the nucleus of the solitary tract (Figure 32–13). In most mammals neurons in this nucleus transmit signals to the parabrachial nucleus of the pons, which in turn sends gustatory information to the ventroposterior medial nucleus of the thalamus. In primates, however, these neurons transmit gustatory information directly to the taste area of the thalamus.

Taste Information Is Transmitted from the Thalamus to the Gustatory Cortex

From the thalamus taste information is transmitted to the gustatory cortex, a region of the cerebral cortex located along the border between the anterior insula and the frontal operculum (Figure 32–13). The gustatory cortex is believed to mediate the conscious perception and discrimination of taste stimuli. The taste area of the thalamus also transmits information both directly and indirectly to the hypothalamus, a structure that controls feeding behavior and autonomic responses.

Recordings made from neurons in the gustatory cortex indicate that some neurons respond to different classes of tastants, whereas others respond to only one, such as bitter or sweet. It might be that neurons responsive to more than one class of tastants encode information about blends whereas those in gustatory cortex or other areas that respond to single taste categories are involved in innate responses, such as attraction to sweet tastants or aversion to bitter tastants.

Perception of Flavor Depends on Gustatory, Olfactory, and Somatosensory Inputs

Much of what we think of as the flavor of foods derives from information provided by the olfactory system. Volatile molecules released from foods or beverages in the mouth are pumped into the back of the nasal cavity by the tongue, cheek, and throat movements that accompany chewing and swallowing. Although the olfactory epithelium of the nose clearly makes a major contribution to sensations of flavor, such sensations are localized in the mouth rather than in the nose.

The somatosensory system is thought to be involved in this localization of flavors. The coincidence between somatosensory stimulation of the tongue and the retronasal passage of odorants into the nose is assumed to cause odorants to be perceived as flavors in the mouth. Sensations of flavor also frequently have a somatosensory component that includes the texture of food as well as sensations evoked by spicy and minty foods and by carbonation.

Insect Taste Organs Are Distributed Widely on the Body

Like vertebrates, insects have specialized organs for taste. Some of the taste neurons occur in internal mouth parts. Others lie near the mouth on the proboscis, or are scattered on the leg, wing, and oviposition organs.

The gustatory receptors of *Drosophila* are membranespanning receptors that are very distantly related to the odorant receptors of the fly. The fly has approximately 60 gustatory receptor genes, a surprisingly large number considering it has approximately 60 olfactory receptor genes. Members of the gustatory receptor gene family are expressed in all of the different kinds of taste organs. Some occur in particular cell types, whereas others are present in many parts of the body.

As in vertebrates, in flies numerous taste receptor genes appear to be expressed in a single neuron. Sweet-sensing and bitter-sensing neurons in the labial palp mediate food acceptance or rejection, respectively. Other neurons have distinct functions. For example, neurons in the male leg express gustatory receptors that are involved in recognizing females during courtship.

An Overall View

The senses of smell and taste allow us to evaluate volatile molecules in our environment and both volatile and nonvolatile components of foodstuffs. Humans

can perceive a vast number of volatile chemicals as having a distinct odor and distinguish odorants with nearly identical structures.

The basic design and functional capacities of olfactory systems are highly conserved across vertebrate species and to some extent in invertebrates. In addition to providing a means of distinguishing between appropriate and potentially harmful substances prior to ingestion, the sense of smell also plays an important role in predator-prey relationships as well as the regulation of social relationships critical to reproduction and the rearing of offspring.

Odorant detection in the nose is mediated by hundreds of different odorant receptors, each expressed by a subset of neurons. Different combinations of odorant receptors detect specific odorants and encode their identities. In the olfactory epithelium neurons with the same receptor are randomly distributed throughout one spatial zone. In the olfactory bulb the axons of neurons with the same type of receptor all converge in a few glomeruli, such that each glomerulus and its associated relay neurons are dedicated to one type of odorant receptor. Thus in the nose the code for an odorant is dispersed across an ensemble of neurons, each expressing one receptor component of the odorant's code, whereas in the olfactory bulb a specific combination of glomeruli receives input from those receptors, an arrangement that is similar in different individuals.

In the olfactory cortex neurons responsive to a given odorant are distributed broadly, but the underlying organization of sensory inputs is unknown. The olfactory cortex transmits information to a variety of other brain areas, including higher cortical areas involved in perception and the hypothalamus, which controls appetite and other basic drives.

Pheromones that elicit innate behavioral or physiological responses are detected in the nasal olfactory epithelium as well as in the vomeronasal organ, an olfactory structure present in most mammals, although not in humans. The vomeronasal organ has two different families of chemosensory receptors. The organization of inputs from these receptors resembles that seen for odorant receptors, but vomeronasal signals travel through a separate neural pathway that targets the hypothalamus but not cortical brain areas.

Humans can distinguish five taste qualities: bitter, salty, sweet, sour, and umami. Salty and sour taste detection is thought to involve specific ion channels, whereas the other three taste qualities derive from G protein-coupled receptors. Three classes of receptors are expressed by separate subsets of taste cells, but a single taste cell expresses many or all of the T2R bitter receptors. Studies in transgenic mice indicate that

innate attraction to sweet tastants and aversion to bitter tastants involve hardwired neural pathways that link different subsets of taste cells on the tongue to different behavioral outcomes. The perception of blends of tastants may involve the gustatory cortex, where some neurons can respond to more than one class of tastants.

Studies of flies and worms have revealed a striking similarity to mammals in the strategies used to detect and distinguish chemicals in the external environment. In the fruit fly *Drosophila* and the nematode *C. elegans*, large families of receptors mediate the detection of environmental chemicals. Although the neural circuits that carry inputs from these receptors differ from those in mammals, they have certain features in common with mammals, suggesting that studies of these relatively simple organisms could provide insight into mechanisms underlying chemosensation in vertebrates as well as invertebrates. Because odors and tastes often elicit innate behaviors in these organisms, they also provide a means of exploring neural circuits that mediate instinctive behaviors.

Part VI

Preceding Page The characteristic movement of a musician's hand is captured in a painting by Giacomo Balla from 1912, "The Hand of the Violinist". Balla studied violin as a boy and, like his contemporaries in the Futurist movement, was interested in depicting motion and speed. The rhythmic brushstrokes evoke the energy of the performer and the vibrations of the music. (Reproduced, with permission, from the Copyright 2011 Artists Rights Society (ARS), New York/SIAE, Rome; and the Bridgeman Art Library International, NY.)

VI Movement

HE CAPACITY FOR MOVEMENT, as many dictionaries remind us, is a defining feature of animal life. As Sherrington, who pioneered the study of the motor system pointed out, "to move things is all that mankind can do, for such the sole executant is muscle, whether in whispering a syllable or in felling a forest."

The immense repertoire of motions that humans are capable of stems from the activity of some 640 skeletal muscles—all under the control of the central nervous system. After processing sensory information about the body and its surroundings, the motor centers of the brain and spinal cord issue neural commands that effect coordinated, purposeful movements.

The task of the motor systems is the reverse of the task of the sensory systems. Sensory processing generates an internal representation in the brain of the outside world or of the state of the body. Motor processing begins with an internal representation: the desired purpose of movement. Critically, however, this internal representation needs to be continuously updated by internal (efference copy) and external sensory information to maintain accuracy as the movement unfolds.

Just as psychophysical analysis of sensory processing tells us about the capabilities and limitations of the sensory systems, psychophysical analyses of motor performance reveal regularities and invariances in the control rules used by the motor system.

Because many of the motor acts of daily life are unconscious, we are often unaware of their complexity. Simply standing upright, for example, requires continual adjustments of numerous postural muscles in response to the vestibular signals evoked by miniscule swaying. Walking, running, and other forms of locomotion involve the combined action of central pattern generators, gated sensory information, and descending commands, which together generate the complex patterns of alternating excitation and inhibition to the appropriate sets of muscles. Many actions, such as serving a tennis ball or executing an arpeggio on a piano, occur far too quickly to be shaped by sensory feedback. Instead, centers, such as the cerebellum, make use of predictive models that simulate the consequences of the outgoing commands and allow very short latency corrections. Motor learning provides one of the most fruitful subjects for studies of neural plasticity.

Motor systems are organized in a functional hierarchy, with each level concerned with a different decision. The highest and most abstract level, likely requiring the prefrontal cortex, deals with the purpose of a movement. The next level, which is concerned with the formation of a motor plan, involves interactions between the posterior parietal and premotor areas of the cerebral cortex. The premotor cortex specifies the spatial characteristics of a movement based on sensory information from the posterior parietal cortex about the environment and about the position of the body in space. The lowest level of the hierarchy coordinates the spatiotemporal details of the muscle contractions needed to execute the planned movement. This coordination is executed by the primary motor cortex, brain stem, and spinal cord. This serial view has heuristic value, but evidence suggests that many of these processes can occur in parallel.

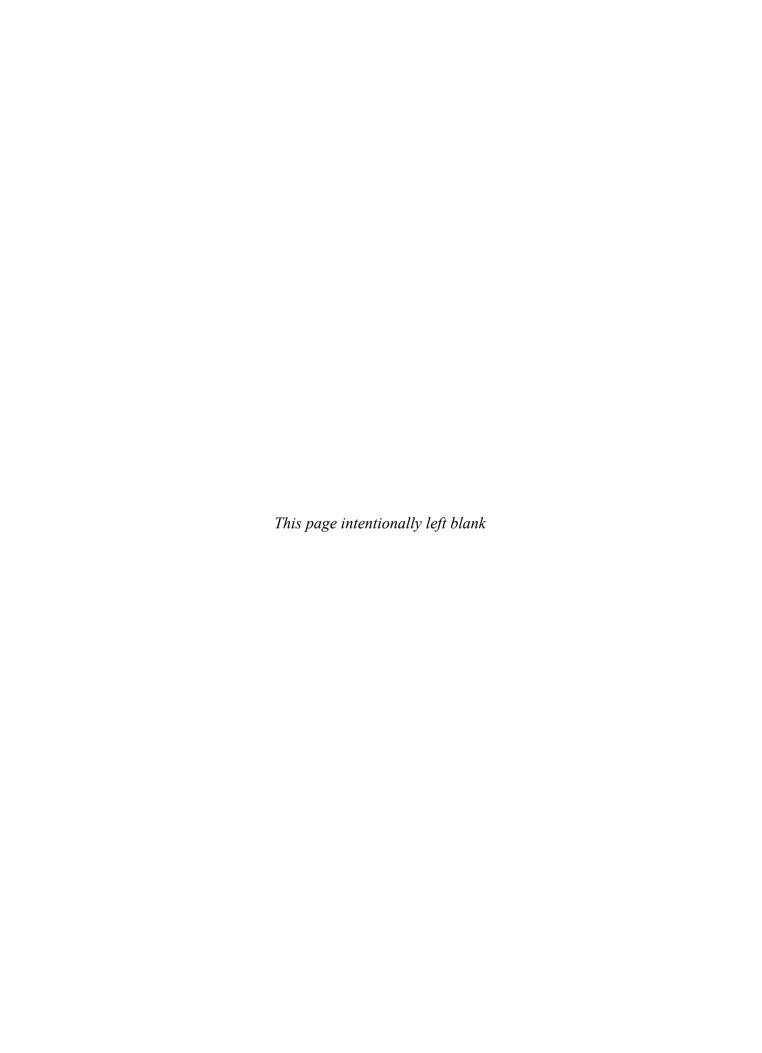

Some functions of the motor systems and their disturbance by disease have now been described at the level of the biochemistry of specific transmitter systems. In fact, the discovery that neurons in the basal ganglia of parkinsonian patients are deficient in dopamine was the first important clue that neurological disorders can result from altered chemical transmission. Imaging techniques can provide information as to how local transmitter abnormalities can lead to widespread changes in the networks involved in the selection and control of movements.

Understanding the functional properties of the motor system is not only fundamental in its own right, but it is of further importance in helping us to understand disorders of this system and explore the possibilities for recovery. As would be expected for such a complex apparatus, the motor system is subject to various malfunctions. Lesions at different levels in the motor hierarchy produce distinctive symptoms, including the movementslowing characteristic of disorders of the basal ganglia, such as parkinsonism, the incoordination seen with cerebellar disease, and the spasticity and weakness typical of spinal damage. For this reason, the neurological examination of a patient inevitably includes tests of reflexes, gait, and dexterity, all of which provide information about the status of the nervous system. In addition to pharmacological therapies, the treatment of neurological disease has recently been augmented by two new approaches. First, focal stimulation of the basal ganglia has been discovered to restore motility to certain patients with Parkinson disease; such deep-brain stimulation is also being tested in the context of other neurological conditions. And second, the motor systems have become a target for the application of neural prosthetics; neural signals are decoded and used to drive mechanical devices that aid patients with paralysis caused by spinal cord injury and stroke.

An Overall View

In the Preceding Part of this book we considered how the brain constructs internal representations of the world around us. These internal representations have no intrinsic value and are behaviorally meaningful only when used to guide movement, whether

foraging for food or attracting a waiter's attention. Thus the ultimate function of the sensory representations is to shape the actions of the motor systems. Sensory representations are the framework in which the motor systems plan, coordinate, and execute the motor programs responsible for purposeful movement.

In this part of the book we describe the principles of motor control that allow the brain and spinal cord to maintain balance and posture; to move our body, limbs, and eyes; and to communicate through speech and gesture.

Although movements are often classified according to function—eye movements, prehension (reach and grasp), posture, locomotion, breathing, and speech—many of these functions are subserved by overlapping groups of muscles. In addition, the same groups of muscles can be controlled voluntarily, rhythmically, or reflexively. For example, the muscles that control respiration can be used to take a deep breath voluntarily before diving under water, to breathe automatically and rhythmically in a regular cycle of inspiration and expiration, or to act reflexively in response to a noxious stimulus in the throat, producing a cough.

Voluntary movements are those that are under conscious control by the brain. Rhythmic movements can also be controlled voluntarily, but many such movements differ from voluntary movements in that their timing and spatial organization is to a large extent controlled autonomously by spinal or brain stem circuitry. Reflexes are stereotyped responses to specific stimuli that are generated by simple neural circuits in the spinal cord or brain stem. Although reflexes are highly adaptable to changes in behavioral goals, mainly because several different circuits

exist to connect sensory and motor neurons, they cannot be directly controlled voluntarily.

In this chapter we focus on voluntary movements, using arm and hand movements to illustrate principles of sensorimotor control. Reflexes and rhythmic movements are discussed in detail in Chapters 35 and 36.

Conscious processes are not necessary for moment-to-moment control of movement. Although we may be aware of the intent to perform a task or of planning certain sequences of actions and at times are aware of deciding to move at a particular moment, movements generally seem to occur automatically. We carry out the most complicated movements without a thought to the actual joint motions or muscle contractions required. The tennis player does not consciously decide which muscles to use to return a serve with a backhand or which body parts must be moved to intercept the ball. In fact, thinking about each body movement before it takes place can disrupt the player's performance.

In this chapter we review the principles that govern the neural control of movement using concepts derived from behavioral studies and from computational models that are used both to understand the brain and to control the movements of robots. First, we look at how the brain transforms sensory inputs into motor outputs through a cascade of sensorimotor transformations. Second, we examine how sensory feedback can be used to correct errors that arise during movement. Finally, we see how motor learning allows us to improve our performance; to adapt to new mechanical conditions, as when using a tool; or to adapt to novel correspondences between sensory and motor events, for example when learning to use a computer mouse to control a cursor.

Motor Commands Arise Through Sensorimotor Transformations

Motor outputs are neural commands that act on the muscles, causing them to contract and generate movement. These outputs are derived from sensory inputs in circuits that represent *sensorimotor transformations*. Sensory inputs include extrinsic information about the state of world as well as intrinsic information about our body. Extrinsic information, for example the spatial location of a target, can be provided by auditory and visual inputs. Intrinsic information includes both kinematic and kinetic information about our body.

Kinematic information includes the position, velocity, and acceleration of the hand, joint angles, and lengths of muscles without reference to the forces that cause

them. *Kinetic information* is concerned with the forces generated or experienced by our body. These different forms of intrinsic information are provided by different sensors. For example, information about muscle lengths and their rate of change is provided mainly by muscle spindles, whereas Golgi tendon organs in the muscles and mechanoreceptors in our skin provide information about the force we are exerting.

Simple reflexes, such as a tendon-jerk reflex, involve a simple sensorimotor transformation: Sensory inputs cause motor output directly without the intervention of higher brain centers. However, voluntary movement requires multistage sensorimotor transformations. The involvement of multiple processing centers actually simplifies processing: Higher levels plan more general goals, whereas lower levels concern themselves with how these goals can be implemented.

Such a hierarchy accounts for the fact that a specific motor action, such as writing, can be performed in different ways with more or less the same result. Handwriting is structurally similar regardless of the size of the letters or the limb or body segment used to produce it (Figure 33–1). This phenomenon, termed *motor equivalence*, suggests that purposeful movements are represented in the brain abstractly rather than as sets of specific joint motions or muscle contractions. Such abstract representations of movement, able to drive different effectors, provide a degree of flexibility of action not practical with preset motor programs.

How do sensorimotor transformations generate movement to a desired location? For a person to reach toward an object, sensory information about the target's location must be converted into a sequence of muscle actions leading to joint rotations that will bring the hand to the target.

First, the target is localized in space relative to some part of the body such as the head or arm (egocentric space). Several sources of information are combined in this process. For example, the location of the target relative to the head is computed from the location of the target on each retina together with the direction of gaze of the eyes (Figure 33–2A). A person also needs to know the initial location of his hand or the tip of the tool that he wishes to place on the target (the endeffector or endpoint). The initial location of the endpoint can be estimated by combining visual inputs, proprioceptive signals, and tactile sensations, each of which can provide location information. Once the current configuration of the arm and location of the target are calculated, a movement can be planned. A plan typically has to specify both a particular path, the successive spatial positions of the endpoint, and also the The ability of different motor systems to achieve the same behavior is called motor equivalence. For example, writing can be performed using different parts of the body. The

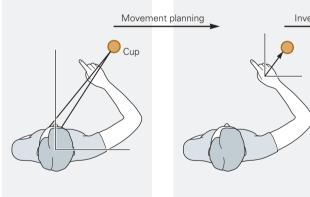

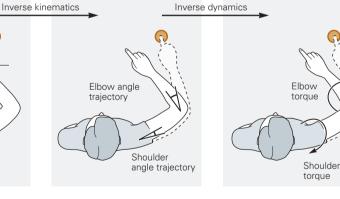

Figure 33-2 Sensorimotor transformations used to generate a particular movement. The task of generating a goal-directed movement is often broken down into a set of sequential stages, the details of which are still being elucidated. The figure shows one possible set of stages to generate a reaching movement, and the arrows indicate the processes

A. Spatial orientation. To reach for an object, the object and hand are first located visually in a coordinate system relative to the head (egocentric coordinates).

required to move between the stages.

B. Movement planning. The direction and distance the hand must move to reach the object (the endpoint trajectory) are

determined based on visual and proprioceptive information about the current locations of the arm and object.

- C. Inverse kinematic transformation. The joint trajectories that will achieve the hand path are determined. The transformation from a desired hand movement to the joint trajectory depends on the kinematic properties of the arm, such as the lengths of the arm's segments.
- D. Inverse dynamic transformation. The joint torques or muscle activities that are necessary to achieve the desired joint trajectories are determined. The joint torques required to achieve a desired change in joint angles depend on the dynamic properties of the arm such as the mass of the segments.

trajectory, the time course over which these positions will be covered, and thus the accelerations and speeds of the movement (Figure 33–2B).

In a hierarchical model of planning the goal can be expressed in kinematic terms, such as the desired positions and velocities of the hand, or in kinetic terms, such as the force exerted by the hand. Movement can be planned as an *endpoint trajectory*, a desired change in the configuration of the limb expressed in coordinates intrinsic to the limb. Such a coordinate system could determine the change in joint angles or be based on a desired change in proprioceptive feedback. For example, the endpoint trajectory could be defined kinematically as the distance and direction the hand has to move to reach the target, as well as the speed along the path to the target.

Transformations can be expressed as changes in kinematic variables, such as the position of the hand and the joint angles that place the hand at that position. The calculation of an endpoint from a set of joint angles is termed *forward kinematic transformation*, whereas calculation of a set of joint angles that can reach an endpoint is termed *inverse kinematic transformation* (Figure 33–2C). This transformation must take into account the geometric parameters of the arm, such as the lengths of the upper arm and forearm (recall that kinematics considers motion without reference to the forces that cause it). The motor system controls joint angle by activating muscles that produce torques (rotational forces) at the joint.

The action of motor commands on muscles that results in a set of angular positions and velocities is known as the forward dynamic transformation. The term "dynamic" refers to the forces required to cause motion. However, to generate a desired joint angle trajectory the system must convert kinematic parameters into motor commands. That is, the system must calculate the torques at each joint necessary to achieve the motion and relate the force required to cause this motion to the desired acceleration of the limb. This transformation is known as the inverse dynamic transformation (Figure 33-2D). In general, to cause any acceleration the forces applied must exceed any resistive forces arising from the viscosity or stiffness of the limb, from gravity, and from external loads. The force not required to overcome the total resistive force will cause an angular acceleration, with the acceleration being dependant on the limb's inertia; the lower the inertia, the higher the acceleration.

Thus through a series of sensorimotor transformations, sensory input is finally converted into muscle contractions that generate movement. Although we have described one possible series of transformations that can achieve a movement, the actual computations used by the central nervous system are still under active investigation.

The Central Nervous System Forms Internal Models of Sensorimotor Transformations

We know from cellular studies that the central nervous system contains internal representations ("neural maps") of the various sensory receptor arrays and the musculature. Experimental and modeling studies strongly suggest that the central nervous system also maintains internal representations that relate motor commands to the sensory signals expected as a result of movement.

Given the fixed lengths of our limb segments, there is a mathematical relationship between the joint angles of the arm and the location of the hand in space. A neural representation of this relationship allows the central nervous system to estimate hand position if it knows the joint angles and segment lengths. The neural circuits that compute such sensorimotor transformations are examples of *internal models* (Box 33–1). Such neural representations may not exactly match true relationships because of structural differences (the models only approximate the true relationship between joint angles and hand position) or errors in the model's parameters (incorrect estimates of segment lengths).

An internal model that represents the causal relationship between actions and their consequences is called a *forward model* because it estimates future sensory inputs based on motor outputs. A forward model anticipates how the motor system's state will change as the result of a motor command. Thus, a copy of a descending motor command acting on the sensorimotor system is passed into a forward model that acts as a neural simulator of the musculoskeletal system moving in the environment. This copy of the motor command is known as an *efference copy* (or corollary discharge) to signify that it is a copy of the efferent signal flowing from the central nervous system to the muscles. We will see later how such simulations can be learned and used in sensorimotor control.

An internal model that calculates motor outputs from sensory inputs is known as an *inverse model*. Such a model can determine what motor commands are needed to produce the particular movements necessary to achieve a desired sensory consequence.

Forward and inverse models can be better understood if we place the two in series. If the structure and parameter values of each model are correct, the output of the forward model (the predicted behavior) will be the same as the input to the inverse model (the desired behavior) (Figure 33–3).

Box 33-1 Internal Models

The utility of numerical models in the physical sciences has a long history. Numerical models are abstract quantitative representations of complex physical systems. Some start with equations and parameters that represent initial conditions and run *forward*, either in time or space, to generate physical variables at some future state. For example, we can construct a model of the weather that predicts wind speed and temperature two weeks from now. In general, the algorithms and parameters of the model should lead to one correct answer.

Other models start with a state, a set of physical variables with specific values, and operate in the *inverse* direction to determine what parameters in the system account for that state. When we fit a straight line to a set of data points, we are constructing an inverse model that estimates slope and intercept based on the equations of the system being linear. An inverse model may thus inform us how to set the parameters of the system to obtain desired outcomes.

Over the last 50 years the idea that the nervous system has similar predictive models of the physical world to guide behavior has become a major issue in neuroscience. The idea originated in Kenneth Craik's notion of *internal models* for cognitive function. In his 1943 book, *The Nature of Explanation*, Craik was perhaps the first to

suggest that organisms make use of internal representations of the external world:

"If the organism carries a 'small-scale model' of external reality and of its own possible actions within its head, it is able to try out various alternatives, conclude which is the best of them, react to future situations before they arise, utilize the knowledge of past events in dealing with the present and future, and in every way to react in a much fuller, safer, and more competent manner to the emergencies which face it."

In this view an internal model allows an organism to contemplate the consequences of current actions without actually committing itself to those actions.

Considering the human body from the viewpoint of sensorimotor control, we should ask two fundamental questions. First, how can we generate actions on the system so as to control its behavior? Second, how can we predict the consequences of our actions?

The central nervous system must exercise both control and prediction to achieve skilled motor performance. Prediction and control are two sides of the same coin, and the two processes map exactly onto forward and inverse models. Prediction turns motor commands into expected sensory consequences, whereas control turns desired sensory consequences into motor commands.

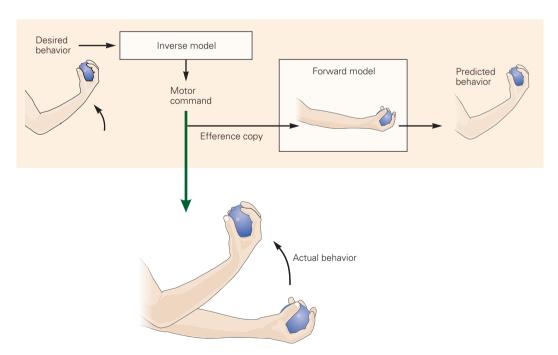

Figure 33–3 Internal models represent relationships of the body and external world. The inverse model determines the motor commands that will produce a behavioral goal, such as raising the arm while holding a ball. A descending motor command acts on the musculoskeletal system to produce the movement. A copy of the motor command is passed to

a forward model that simulates the interaction of the motor system and the world and can therefore predict behaviors. If both forward and inverse models are accurate, the output of the forward model (the predicted behavior) will be the same as the input to the inverse model (the desired behavior).

Movement Inaccuracies Arise from Errors and Variability in the Transformations

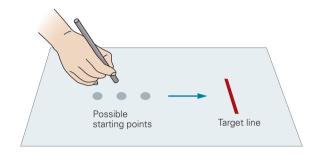

Motor control is often imprecise. Indeed, society celebrates those who can throw a dart into a small area of a board or hit a small white ball into a hole with a club. However, even the movements of the most skilled players show some degree of variability. In the 1890s the psychologist Robert Woodworth showed that fast movements are less accurate than slow ones. People slow their movements when accuracy is demanded. Inaccuracy can arise either from variability in the sensory inputs and motor outputs or from errors in the internal representations of this information.

An important component of sensorimotor variability is the intrinsic variability of our sensors and motor neurons because of fluctuations in their membrane potential. Because of these fluctuations, known as neural noise, the level of input signals required to trigger postsynaptic action potentials also varies. On the input side, neural noise limits the accuracy of estimates of the location of a target or limb (how near an estimate is to the true value) as well as their precision (how accurate the estimate is when repeated). On the output side, neural noise limits the accuracy and precision with which we contract our muscles. Moreover, the amount of noise in motor commands tends to increase with larger motor commands, limiting our ability to move rapidly and accurately at the same time. This increase in variability is caused by random variation in both the excitability of motor neurons and the recruitment of the additional motor units needed to produce increases in force.

Incremental increases in force are produced by progressively smaller sets of motor neurons, each of which produces disproportionately greater increments of force (see Chapter 34). Therefore, as force increases, fluctuations in the number of motor neurons lead to greater fluctuations in force. The consequences of this can be observed experimentally by asking subjects to generate a constant force or a force pulse of fixed amplitude. Not only are subjects unable to maintain constant force, but the variability of force also increases with the level of the force. Over a large range this increase in variability is captured by a constant coefficient of variation (the standard deviation divided by the mean force). This dependence of variability on force corresponds to the increase in the variability of pointing movements with the average speed of movement. The decrease in accuracy of movement with increasing speed is known as the *speed-accuracy trade-off* (Figure 33–4).

Errors can also arise from inaccuracy in the internal models that compute sensorimotor transformations.

Neural representations of the musculature cannot easily capture the complex biomechanical properties of the musculoskeletal system, and this in turn significantly complicates the ability of the brain to compute accurate sensorimotor transformations. Indeed, the dependence of muscle force on the motor command is itself highly complex. A model prescribing motion in a system with just a single joint must not only estimate the muscle

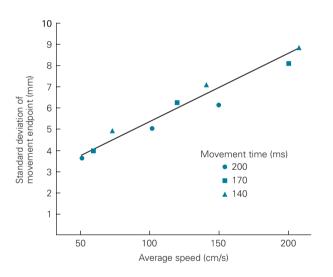

Figure 33-4 Accuracy of movement varies in direct proportion to its speed. Subjects held a stylus and were required to try and hit a target line lying perpendicular to the direction in which they moved. Each subject started from three different initial positions and was required to complete the movement within three different times (140, 170, or 200 ms). A successful trial was one in which the subject completed the movement within 10% of the required time. Only successful trials were used for analysis. Subjects were informed if their movements were more than 10% different from the required duration. The plot shows the variability in the motion of the subjects' arm movements as the standard deviation of the extent of movement versus average speed (for each of three movement starting points and three movement times, giving nine data points). The variability in movement increases in proportion to the speed and therefore to the force producing the movement. (Reproduced, with permission, from Schmidt et al. 1979.)

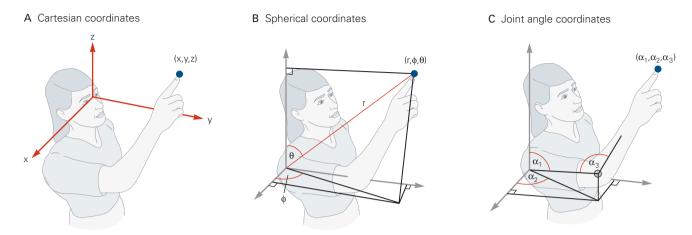

Figure 33–5 The location of the finger in space can be specified in different egocentric coordinate systems.

A. Cartesian coordinates centered on the eyes.

B. Spherical polar coordinates centered on the shoulder (distance r, azimuth ϕ , and elevation θ).

C. An intrinsic coordinate system based on shoulder angles (α_1 and α_2), which relate the orientation of the upper arm to the Cartesian axes, and elbow angle (α_3), which specifies the angle between the upper and lower arm.

force (or torque) but also take into account inertia (the mass resisting acceleration), viscosity (resistive forces proportional to velocity), stiffness (elastic forces proportional to displacement) produced by the muscles and tendons opposing movement, and gravity.

The dynamic relationship between segments of limbs further complicates sensorimotor transformations. The motion of each segment produces torques, and potentially motions, at all other segments through mechanical interactions. For example, flexion of the upper arm through shoulder rotation can lead to either extension or flexion of the elbow depending on the initial elbow angle. In general, because of the interactions between linked segments, the torques needed to produce a specific change in angle at a particular joint depend not only on the muscles acting directly at this joint but also on the configurations and the motions of all other joints, and especially their acceleration. The brain develops an internal model of these complex mechanical interactions through learning early in childhood. We will see later that this learning is updated throughout life and depends critically on proprioception, which provides the brain with information about changes in muscle length and joint angles.

Different Coordinate Systems May Be Employed at Different Stages of Sensorimotor Transformations

Different coordinate systems are used in sensorimotor transformations and are encoded in several brain regions. Coordinate systems are either extrinsic or intrinsic to the body. Extrinsic coordinate systems relate objects in the outside world to other objects (allocentric coordinates) or to our body (egocentric coordinates) using exteroceptive information, usually visual or auditory (Figures 33–5A and B). Intrinsic coordinate systems, such as the set of muscle lengths or set of joint angles (Figure 33–5C), are based on information provided primarily by proprioceptive systems.

Elucidating the coordinate systems used in sensorimotor transformations is a major endeavor in neuroscience. We will see in later chapters that this issue can be fruitfully studied by examining how the firing patterns of neurons in different parts of the brain encode task features or movement parameters. Such studies aim to determine the variables (such as position or velocity) or type of coordinate system (such as allocentric or egocentric) that the neurons encode.

Behavioral studies also have used a variety of methods to examine the coordinate systems used in directing movement. One way has been to examine the details of the errors made during movement in different tasks. When subjects are asked to reach rapidly and repeatedly to a target, the error in the movements can be measured in different ways. If we average the final location of the hand across many trials, we may find a constant error or bias in the movement. We can examine the distribution of the final locations of the hand about this average position and infer from the patterns

of constant and variable error the coordinate system used in the movement (Box 33–2).

Stereotypical Patterns Are Employed in Many Movements

Given a task, motor plans are underconstrained. For example, the hand can move to a target along an infinite number of possible paths, and for each path there

is an infinite number of trajectories. Having specified the path and velocity, each point along the path could be reached by any number of combinations of arm joint angles and, owing to the overlapping actions of muscles and the ability to co-contract, each arm configuration could be achieved by many different combinations of muscles.

Although we have described different types of sensorimotor transformations, in general the inverse

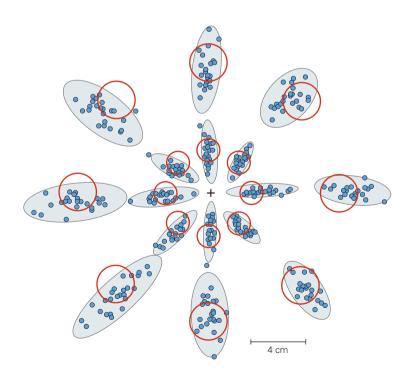

Box 33-2 The Brain's Choice of Spatial Coordinate System Depends on the Task

When subjects are shown a visual target and asked to reach for it repeatedly, the pattern of errors they make varies with the circumstance of the task. By examining these errors it is possible to assess which coordinate system is used to represent the target position under different conditions.

For example, when subjects are required to move their hands on a horizontal surface and can estimate the starting position of their hands before movement, the pattern of errors indicates planning in "hand-centered" coordinates. The distributions of the endpoints of the movements demonstrate that, under the conditions of the task, errors in distance and direction are independent of each other (Figure 33–6) and thus that errors in the extent of a movement cannot be predicted from errors in direction. The independence of the two types of errors suggests that for this type of task subjects estimate distance and direction relative to a specific starting location (that is a movement vector) in Cartesian coordinates.

Conversely, when subjects make large threedimensional movements to remembered visual targets in the dark, a different pattern of error is observed.

Figure 33-6 Errors in distance and direction of movement are independent of each other. Distribution of endpoints for reaching movements to 16 targets (eight directions and two distances) by one subject. Targets (red circles) were presented 24 times in random order, and each time the subject was asked to place a finger on the target. All movements begin from a central starting position (designated +). Endpoints for individual movements are represented by blue dots. The endpoints for the reaches to each target are fitted with an ellipse, demonstrating that errors in distance and direction are independent of each other. (Adapted, with permission, from Gordon, Ghilardi, and Ghez 1994.)

transformations cannot be uniquely specified. For example, the inverse kinematic transformation that transforms hand positions into joint angles can have many outputs based on the same input. This is because many different combinations of joint angles will put the hand in the same place. The ability of the motor systems to achieve a task in many different ways is called *redundancy*. If one way of achieving a task is not practical, there is usually an alternative.

Some of the earliest studies of movement examined how the brain determines the duration of a movement. Fitts's law describes the relationship between the amplitude, accuracy, and duration of a movement. This law relates the duration of a movement to the accuracy required of the task, as determined by the target width and amplitude of the movement, and applies to a variety of tasks such as reaching, placing pegs in holes, and picking up objects (Figure 33–8).

When the target and finger locations at the end of the reach are plotted against each other in terms of spherical coordinates centered on the shoulder, angular errors (elevation and azimuth) are small, whereas errors in the radial extent of the movement are significant (Figure 33–7). Moreover, the two types of errors are not correlated. However, if the target and finger locations are plotted in terms of spherical coordinates centered on the head, the errors are correlated.

The fact that the spherical coordinate system centered on the shoulder produces uncorrelated errors suggests that at some stage in the sensorimotor transformation the target is represented in shoulder-centered coordinates. Recent work suggests that this pattern of errors reflects planning for a final hand position rather than a particular hand trajectory.

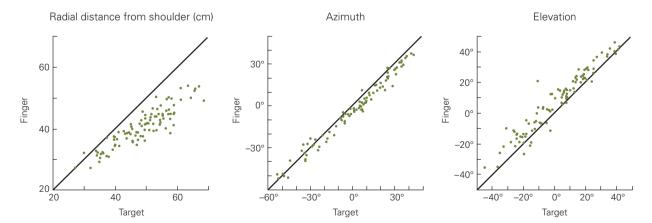

Figure 33–7 Distance errors are greater than direction errors for movements in the dark. A subject was asked to place a finger on the remembered location of a target in the dark. Final finger position and target location are plotted in spherical coordinates centered on the shoulder

(see Figure 33–5B). The straight line represents perfect performance and the dots individual reaching movements. Radial distance errors and angular errors (azimuth and elevation) are plotted separately. (Adapted, with permission, from Soechting and Flanders 1989.)

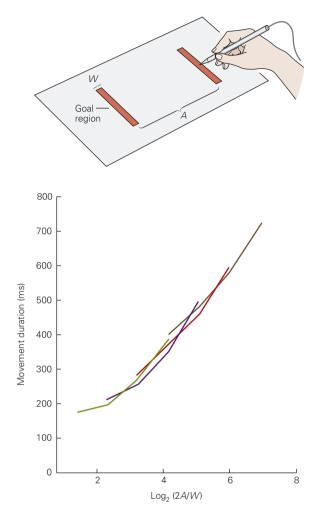

Figure 33–8 Fitts's law describes the speed-accuracy trade-off. Subjects were required to move a stylus between two targets of width W separated by distance A. The width of the targets was changed on each trial. Each line in the plot represents the results for a different target width (from narrow to wide) over four different movement amplitudes. Subjects were required to move as fast as possible while still hitting the targets. Over a large range of target widths and distance between targets, movement duration is linearly dependent on $\log_2{(2A/W)}$, the index of difficulty. (Adapted, with permission, from Jeannerod 1988.)

Despite variations in movement direction, speed, and location, several aspects of reaching movements are stereotypical or invariant. First, the hand tends to follow roughly a straight path (Figure 33–9A), although significant curvature is observed for certain movements, particularly vertical movements and movements near the boundaries of the reachable space. The tendency to make straight-line movements characterizes a large class of movements and is surprising given that the

muscles act to rotate joints. Second, a plot of hand speed over time is typically smooth, unimodal, and roughly symmetric (bell-shaped) (Figure 33–9B). This is not the case when movement accuracy requirements are high or corrections to the movement are made.

In contrast, the motions of the joints in series (such as the shoulder, elbow, and wrist) are complicated and vary greatly with different initial and final positions. Because rotation at a single joint would produce an arc at the hand, both elbow and shoulder joints must be rotated concurrently to produce a straight path. In some directions the elbow moves more than the shoulder; in others, the reverse occurs. When the hand is moved from one side of the body to the other (see Figure 33–9A, movement from T2 to T5) one or both joints may have to reverse direction in midcourse. The fact that hand trajectories are more invariant than joint trajectories suggests that the motor system typically controls the hand by adjusting joint rotations and torques to achieve desired hand trajectories.

Invariances can also be seen in more complex movements. The nervous system puts together complex actions from elemental movements that have highly stereotyped spatial and temporal characteristics. For example, the seemingly continuous motion of drawing a figure eight actually consists of several discrete movements that are roughly constant in duration, regardless of their size. Moreover, there is a relationship between the curvature of each elemental movement and speed: Subjects tend to slow the hand as the curvature of the path increases. Empirical studies have shown that for many tasks a power law relation, the two-thirds power law, governs the relationship between hand speed and path curvature (Figure 33–10).

The simple spatiotemporal elements of a complex movement are called movement primitives or *movement schemas*. Like the simple lines, ovals, or squares in computer graphics programs, movement schemas can be scaled in size or time. The neural representations of complex actions, such as prehension, writing, typing, or drawing, are thought to be stored sets of these simple spatiotemporal elements.

Recent computational studies of a variety of tasks suggest that a repertory of movement schemas is the result of a process in which all possible ways of moving are ranked and the best is selected. This idea implies that either through evolution or motor learning our movements improve progressively until some limit is reached.

To quantify how good or bad a movement the brain assigns a cost to each possible movement, and the movement with the lowest cost is executed. The cost is specified as some function of the movement and task, and the challenge to researchers has been to determine, from observed movement patterns and perturbation studies, the form of this function.

The cost may be kinematic; for example, lack of smoothness in a movement can be corrected by minimizing the rate of change of hand acceleration summed over a movement. Alternatively, the cost may be dynamic. For example, because the variability in the motor output is proportional to the magnitude of the motor command, repetition of the same sequence of intended motor commands many times will lead to a distribution of actual movements. Modifying the sequence of motor commands can control aspects of

this distribution, such as the spread of positions of the hand at the end of the movement. In a simple aiming movement the cost is the final error, as measured by the variability about the target. A model that minimizes this cost would accurately predict the trajectories of both eye and arm movements.

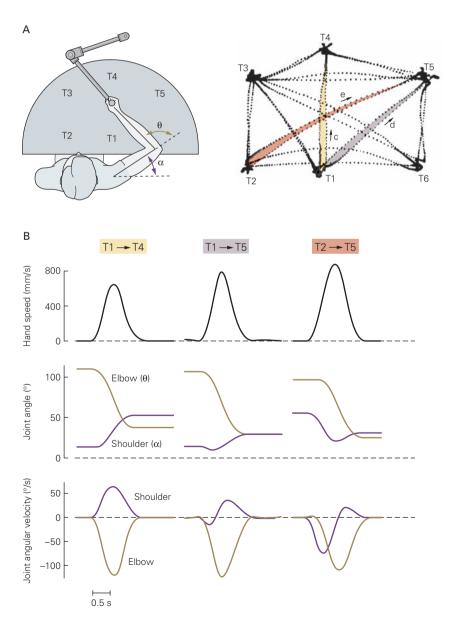

Motor Signals Are Subject to Feedforward and Feedback Control

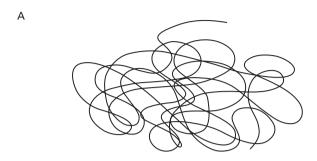

So far we have focused on how sensory inputs are used to plan a movement and why the resulting movements

Figure 33–9 Hand path and velocity have stereotypical features. (Adapted, with permission, from Morasso 1981.)

A. The subject sits in front of a semicircular plate and grasps the handle of a two-jointed apparatus that moves in one plane and records hand position. The subject is instructed to move the hand between various targets (T1–T6). The record on the right shows the paths traced by one subject.

B. Kinematic data for three hand paths shown in part A (c, d, and e). All paths are roughly straight, and all hand speed profiles have the same shape and scale in proportion to the distance covered. In contrast, the profiles for the angular velocity of the elbow and shoulder for the three hand paths differ. The straight hand paths and common profiles for speed suggest that planning is done with reference to the hand because these parameters can be linearly scaled. Planning with reference to joints would require computing nonlinear combinations of joint angles.

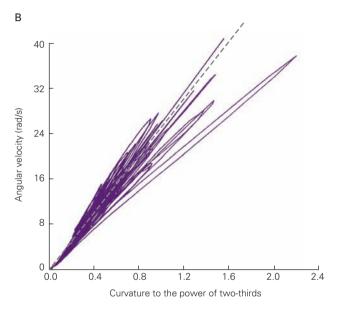

Figure 33–10 Complex movements obey the two-thirds power law. (Reproduced, with permission, from Lacquaniti, Terzuolo, and Viviani 1983.)

A. Nondirected scribbling is a complex movement.

B. Instantaneous values of the angular velocity of the hand while scribbling are plotted against the curvature of the hand's path raised to the power of two-thirds. The relation between the two variables is piecewise linear. Each segment in the bundle, corresponding to nonoverlapping segments of the trajectory, has a different slope. The slopes cluster around the average (dashed line), a typical result for this type of experiment. Therefore the relationship between the speed of hand motion and the degree of curvature of the hand path is roughly constant: Velocity varies as a continuous function of the curvature raised to the power of two-thirds. This two-thirds power law governs virtually all movements and expresses an obligatory slowing of the hand during movement segments that are more curved and a speeding up during segments that are straight. Because angular velocity is the speed of the hand multiplied by the path curvature, in the plot an increase in angular velocity represents a decrease in hand speed.

can have errors. Sensory inputs to the motor systems during a movement provide information about errors that arise from neural noise, from inaccuracies in the motor commands as a result of flaws in the internal models, or from changes in the outside world, such as the unexpected motion of a target. We now examine what part these errors play in two forms of motor control, feedforward and feedback control.

Feedforward Control Does Not Use Sensory Feedback

Movements that are not correctible during the movement are often termed *ballistic*. This term is ordinarily applied to the trajectory of unpowered projectiles (such as ballistic missiles) that, once launched, can no longer be controlled and are subject only to gravity. Because arm movements can potentially be controlled throughout their course, however, the term *feedforward control* more accurately describes the trajectory. Feedforward commands are generated without regard to the consequences. Such commands are also termed *open-loop* because the sensorimotor loop is not completed by sensory feedback (Figure 33–11A).

Open-loop control is advantageous if we consider the delays inherent in the sensorimotor system. Both conversion of stimulus energy into neural signals by stimulus receptors and conveyance of the sensory signals to central neurons take time. For example, visual feedback can take approximately 100 ms to be processed in the retina and transmitted to the visual cortex. In addition to delays in the peripheral sensory system, there are also delays in central processing, in the transmission of efferent signals to motor neurons, and in the response of muscles. In all, the combined sensorimotor loop delay is appreciable, approximately 200 ms for a response to a visual stimulus. This delay means that rapid movements, such as the saccades of the eye that last less than 100 ms, cannot use sensory feedback to guide the eye onto a target.

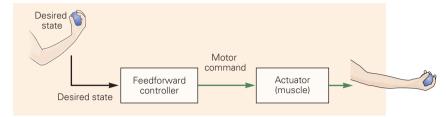

Even with slower movements, such as deliberate reaching, which can take approximately 500 ms, sensory information cannot be used to guide the initial part of a movement, so open-loop control must be used. This open-loop component can be clearly demonstrated. Both the initial speed and the acceleration of the hand during reaching are proportional to the distance of the target. This and the straightness of hand paths mean that the extent of a movement is planned before the movement is initiated, and the movement is generated in a feedforward manner (Figure 33–12).

Open-loop control also has disadvantages. Any movement errors caused by inaccuracies in planning

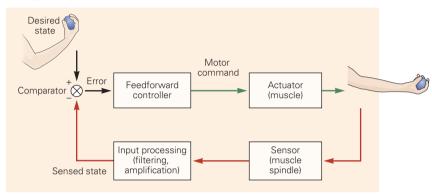

Figure 33–11 Feedforward and feedback control.

- **A.** A feedforward controller generates a motor command based on a desired state. Any errors that arise during the movement are not monitored.
- B. With feedback control the desired and sensed states are compared (at the comparator) to generate an error signal, which helps shape the motor command. There can be considerable delay in the feedback of sensory information to the comparator.

A Feedforward control

B Feedback control

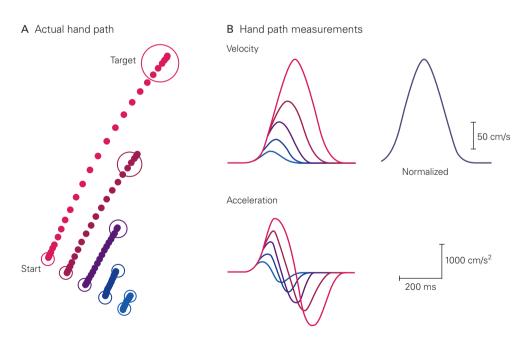

Figure 33–12 Acceleration and velocity of reaching are a function of target distance. (Modified, with permission, from Gordon et al. 1994.)

- **A.** Hand paths measured to targets located 2.5, 5, 10, 20, and 30 cm from the starting position.
- **B.** Average velocity and acceleration of the hand movements shown in part A. The acceleration and velocity profiles scale

linearly as a function of the distance to the target. All the velocity profiles are self-similar and when normalized in time and amplitude are nearly identical. The single peaks indicate that the extent of movement is specified prior to actual movement. If it were not, the first peak would be the same for all target distances, and secondary peaks representing feedback adjustment would be seen.

or execution will not be corrected, and therefore will compound themselves over time or successive movements. The more complex the system under control, the more difficult it is to arrive at a perfect inverse model through learning. For example, the vestibulo-ocular reflex (see Chapter 40) uses open-loop control to maintain fixation during head rotation. This is a very efficient system as the dynamics of the eye are relatively simple, and the rotation of the head can be directly sensed by the vestibular labyrinth. The complexity of the arm, however, makes it very difficult to optimize an inverse model, and thus the control of hand movement requires some form of error correction.

Feedback Control Uses Sensory Signals to Correct Movements

To correct movement errors as they arise, the action must be monitored before it is completed. Such error-correcting systems are known as feedback or closed-loop systems because the sensorimotor loop is complete (Figure 33–11B).

The simplest form of feedback control is one in which the control system generates a fixed response when the error exceeds some threshold. Such a system is seen in most central heating systems in which a thermostat is set to a desired temperature. When the house temperature falls below the specified level, the heating is turned on until the temperature reaches that level. Although such a system is simple and can be effective, it has the drawback that the amount of heat being put into the house does not relate to the discrepancy between the actual and desired temperature (the error). A better system is one in which the control signal is proportional to the error.

Such proportional control of movement involves sensing the error between the actual and desired position of, for example, the hand. The size of the corrective motor command is in proportion to the size of the error and in a direction to reduce the error. The amount by which the corrective motor command is increased or decreased per unit of positional error is called the *gain* (Figure 33–13). By continuously correcting a movement, feedback control can be robust both to noise in the sensorimotor system and to environmental perturbations.

In most motor systems movement control is achieved through both feedforward and feedback processes. Because sensory feedback is not available for the first portion of a movement, feedforward processes generate the initial motor command only. As the movement progresses, information on performance becomes available, allowing feedback control to play a role.

When lifting an object between thumb and index finger, for example, sufficient grip force (perpendicular force between the digits and the object's surface) must be generated to prevent slippage owing to load force (tangential force between the digit and object surface arising from the object's weight). We use feedforward control to set our grip force and the lifting force in accordance with the expected slipperiness and weight of the object. If cutaneous receptors indicate that slippage is occurring, our grip force is increased immediately through rapid feedback control (Figure 33–14). Because cutaneous information on slippage evokes a motor command to increase grip force only when the object is being lifted, this feedback circuit is said to be "gated" during lifting.

Feedback control cannot generate a command in anticipation of an error: It is always driven by an error. Feedforward control, conversely, is based only on a desired state and can therefore null the error.

Prediction Compensates for Sensorimotor Delays

Accurate feedback control of movement requires information on the body's current state, for example, the positions and velocities of our body segments. However, sensory feedback from the periphery is both noisy and slow. Delays in feedback can lead to problems during a movement, as the delayed information does not reflect the present state of the body and world. Two strategies can compensate for such delays and thus increase the accuracy of sensory feedback during movement: intermittency of movement and prediction of changes in body states due to movement. With intermittency, movement is momentarily interrupted by rest, as in eye saccades and manual tracking. Provided the interval of rest is greater than the time delay of the sensorimotor loop, intermittency fosters more accurate sensory feedback.

Prediction is a better strategy and can form a major component of a state estimator. Although sensory signals provide necessary information about the body, the motor command also provides useful information. If both the current state of the body and the descending motor command are known, the next state of the body can be estimated. This estimate is derived from a forward model that predicts how the body will change in response to the motor command. Because this estimate is predictive, it is time-advanced, thereby compensating for the feedback delays. However, this estimate will tend to drift over time if the forward model is not perfectly accurate.

The drawbacks of using only sensory feedback or only motor prediction can be ameliorated by monitoring

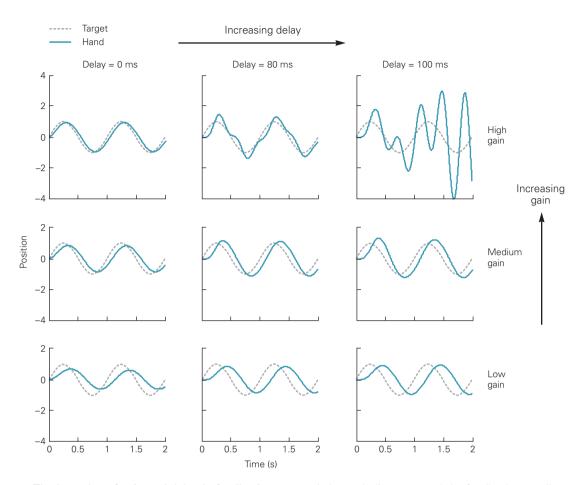

Figure 33–13 The interplay of gain and delay in feedback control. Subjects use a controller to track a target moving sinusoidally in one dimension. The sensory feedback signal that conveys error in the hand's position arrives after some period of time (the delay), and the motor system tries to correct for the error by increasing or decreasing the size of its command relative to the error (the gain).

The plots show the performance of a subject tracking a sinusoidal target in which there is either instantaneous feedback of error (left column) or feedback with a delay (middle and right columns). When the gain is high, and the delay is low, tracking is very good. However, as the delay increases, the motor system corrects for error inappropriately, and this leads to oscillations and large errors. To maintain stability, the gain can be lowered, but tracking is not perfect.

At low gain (bottom row) the feedback controller corrects errors only slowly and tracking is inaccurate. As the gain increases (middle row) the feedback controller corrects errors more rapidly and tracking performance improves. At high gain (top row) the system corrects rapidly but is prone to overcorrect, leading to instability when the time delay in feedback is on the order of physiological time delays (top right). Because the controller is compensating for errors that existed 100 ms earlier, the correction may therefore be inappropriate for the current error. This overcorrection leads to oscillations and is one mechanism proposed to account for some forms of oscillatory tremor seen in neurological disease.

both and using a forward model to estimate the current state of the body. A neural apparatus that does this is known as an *observer model*. The major objectives of the observer model are to compensate for sensorimotor delays and to reduce uncertainty in the estimate of the state of the body owing to noise in both the sensory and motor signals (Figure 33–15). Such a model

has been supported by empirical studies of how the nervous system estimates hand position, posture, and head orientation.

The nervous system has several different internal models of control that use prediction and sensory feedback to different extents. The comparative advantages of these various models are nicely illustrated

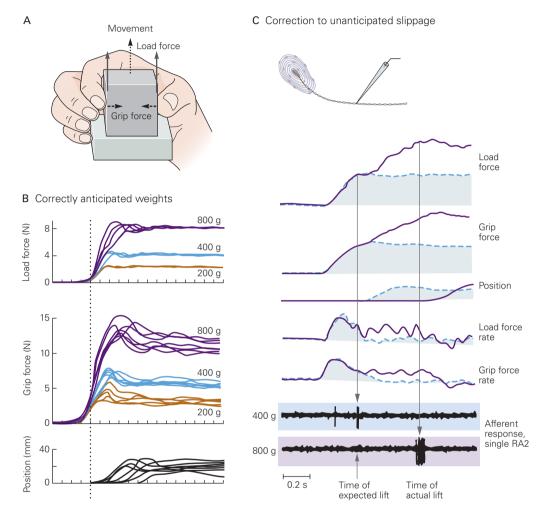

Figure 33–14 Both feedback and feedforward controls are used when lifting an object.

A. The subject lifts an object from the table. Sensory receptors measure vertical motion, grip force, and the load force applied to the object to overcome gravity and inertia. The discharge of different sensory receptors is recorded by microelectrodes inserted within identified sensory axons of the peripheral nerve, a procedure called microneurography.

B. When the subject knows the weight of the object in advance, the applied forces are adequate to lift the object. Three sets of traces (24 trials superimposed) show load force, grip force, and position as subjects lifted three objects of different weights (200, 400, and 800 g). The grip force increases in proportion to the weight of the object. This is done by scaling a

preprogrammed force profile (the profiles have the same shape but different amplitudes).

C. When the weight is larger than expected, the object slips initially, but force is increased before lifting begins. When the subject begins to lift a 400 g object, Pacinian corpuscles in the skin are activated and a burst of action potentials occurs in the afferent RA2 fibers, signaling the beginning of the hold phase during which the grip force is constant. After being presented with the 400 g object for several trials (dashed lines), the subject is given an 800 g object (solid lines). When the subject begins to lift the 800 g object, the object slips, and the RA2 fibers are not activated. The absence of RA2 signals triggers a slow increase in force that is terminated when lifting begins. (Reproduced, with permission, from Johansson et al. 1991.)

by differences in object manipulation under different conditions. When the object's behavior is unpredictable, sensory feedback provides the most useful signal for estimating load. For example, when flying a kite we need to adjust our grip almost continuously in response to unpredictable motions of the kite. When dealing with such unpredictability, grip force needs to be high to prevent slippage because it tends to lag behind load force (Figure 33–16A).

However, when handling objects with stable properties, predictive control mechanisms can be effective. For

example, when the load is increased by a self-generated action, such as moving the arm, the grip force increases instantaneously with load force (Figure 33–16B). Sensory detection of the load would be too slow to account for this rapid increase in grip force. Such predictive control is essential for the rapid movements commonly observed in dexterous behavior.

The discrepancy between actual and predicted sensory feedback is also essential in motor control. For example, when we pick up an object, we anticipate when the object will lift off. The brain is particularly

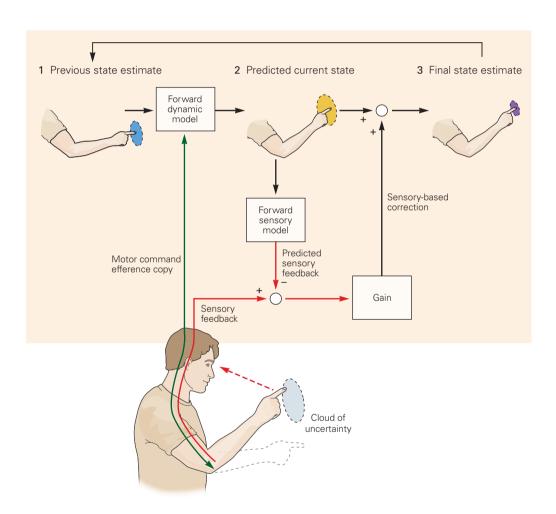

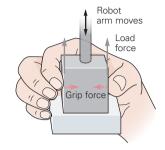

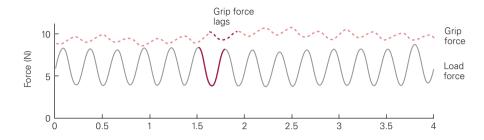

Figure 33–15 An observer model. The drawing shows how the finger's location can be estimated during movement of the arm. A previous estimate of the distribution of possible finger positions (1) is the basis for a new estimate (2). This estimation uses an efference copy of the motor command and a model of the dynamics. The new distribution of estimated finger positions (the "cloud of uncertainty") is larger than that of the previous estimate. The model then predicts the sensory feedback that would occur for these new finger positions, and the error

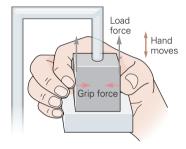

between the predicted and actual sensory feedback is used to correct the estimate of current finger position. This correction changes the sensory error into state errors and also determines the relative reliance on the efference copy and sensory feedback. The final estimate of current finger position (3) has less uncertainty. This estimate becomes the new previous estimate for subsequent movement as this sequence is repeated many times. Delays in sensory feedback that must be compensated have been omitted from the diagram for clarity.

A Robot controls movement

B Hand controls movement

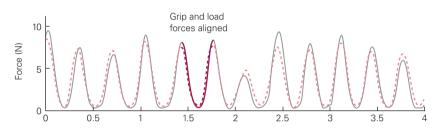

Figure 33–16 Anticipatory control of self-generated actions. (Reproduced, with permission, from Blakemore, Goodbody, and Wolpert 1998.)

A. When a subject is instructed to hold onto an object to which a robot is applying a sinusoidal load force, the grip force of the fingers is high to prevent slippage but nevertheless lags behind the increases in load force.

B. Conversely, when the subject actively pulls down the object, producing a similar load profile, the load force can be anticipated and thus the grip force is lower and tracks the load force without delay.

sensitive to the occurrence of unexpected events or the nonoccurrence of an expected event. Thus if an object is lighter or heavier than expected, and therefore is lifted too early or cannot be lifted, reactive responses are evoked. The brain seems to pay particular attention to these critical moments to determine whether the subsequent actions that are part of the task should proceed.

In addition to its use in compensating for sensory feedback delays, prediction is a key element in perceptual processing. Sensory feedback can originate from two sources: either external sources or our own movement. In the sensory receptor these two sources are not distinguished, however, and sensory signals do not carry a label "external stimulus" or "internal stimulus."

Sensitivity to external events can be amplified by reducing the feedback from our own movement. Thus predictions of sensory signals that arise from our own movements are subtracted from the total sensory feedback, thereby enhancing the signals that carry information about external events. Such a predictive mechanism is responsible for the fact that tickling oneself is a less intense experience than tickling by another. When participants are asked to tickle themselves with a time delay introduced between the motor command and the resulting tickle, the greater the time delay the more ticklish the sensation. As the time delay increases, the predictor becomes more inaccurate, thereby failing to cancel the sensory feedback resulting in the tickle sensation.

Sensory Processing Is Different for Action and Perception

A growing body of research supports the idea that the sensory information used to control actions is processed in neural pathways that are distinct from the afferent pathways that contribute to perception. Mel Goodale and David Milner have proposed that visual information flows in two streams in the brain (see Chapter 25). A dorsal stream projects to the posterior parietal cortex and is particularly involved in the use of vision for action (see Chapter 38). Conversely, a ventral stream projects to the inferotemporal cortex and is involved in conscious visual perception (see Chapter 28).

This distinction between the uses of vision for action and perception is based on a double-dissociation seen in patient studies. For example, the patient D. F. developed visual agnosia after damage to her ventral stream. She is unable, for example, to explain the orientation of a slot either verbally or with her hand. However, when asked to perform a simple action, such as putting a card through the slot, she has no difficulty orienting her hand appropriately to put the card through the slot. Conversely, patients with damage to the dorsal stream can develop optic ataxia in which perception is intact, but control is affected.

Although the distinction between perception and action arose from clinical observations, it can also be seen in normal people, as in the size–weight illusion. When lifting two objects of different size but equal weight, people report that the smaller object feels heavier. This illusion, first documented more than

100 years ago, is both powerful and robust. It does not lessen when a person is informed that the objects are of equal weight and does not weaken with repeated lifting.

When subjects begin to lift large and small objects that weigh the same, they generate larger grip and load forces for the larger object because they assume that larger objects are heavier. After alternating between the two objects, they rapidly learn to scale their fingertip forces precisely for the true object weight (Figure 33–17). This shows that the sensorimotor system recognizes that the two weights are equal. Nevertheless, the size—weight illusion persists, suggesting not only that the illusion is a result of high-level cognitive centers in the brain but also that the sensorimotor system can operate independently of these centers.

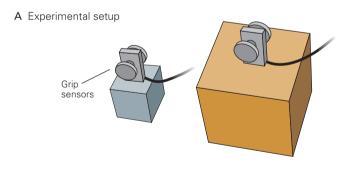

Motor Systems Must Adapt to Development and Experience

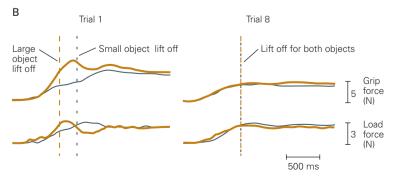

Animals have a remarkable capacity for learning new motor skills through their interaction with the environment. This learning is distinct from and independent of the development of skills through

Figure 33–17 The size–weight illusion. (Reproduced, with permission, from Flanagan and Beltzner 2000.)

A. In each trial subjects lifted first a large object and then a small object that weighed the same. Subjects thought the smaller object felt heavier than it actually was.

B. In the first trial subjects generated greater grip and load forces for the bigger object (orange traces) as it was expected to be heavier than the small object. In the eighth trial the grip and load forces are the same for the two objects, showing that the sensorimotor system generates grip and load forces appropriate to the weights of the two objects despite the conscious perception of a difference in weight.

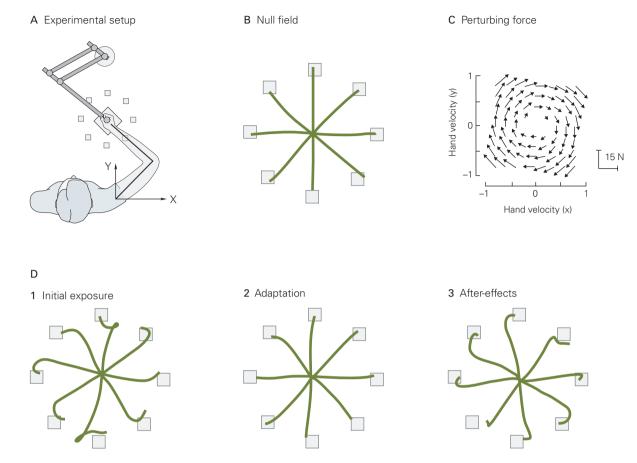

Figure 33–18 Learning improves the accuracy of reaching in a novel dynamic environment.

A. A subject holds an apparatus that measures the position and velocity of the hand and applies forces to the hand. (Reproduced, with permission, from Brashers-Krug, Shadmehr, and Bizzi 1996.)

B. When the motors are off (null field) the subject makes approximately straight movements from the center of the workspace to targets arrayed in a circle.

C. A clockwise force is then applied to the hand, shown as a function of hand velocity. This field produces a force

proportional to the speed of the hand that always acts at right angles to the current direction of motion.

D. Initially the hand paths are severely perturbed in response to the perturbing force (1). After some time the subject adapts and can again follow a straight path during the entire movement (2). When the motors are then turned off, movement is again perturbed but in a direction opposite to the earlier perturbation (3).

maturation. Although evolution can hard-wire some motor behaviors, such as the ability of a foal to stand, motor behavior in general must adapt to new and varying environments.

New motor skills cannot be acquired by a fixed neural control system. Sensorimotor control systems must constantly adapt over a lifetime as body size and proportions change, thereby maintaining an appropriate relationship between motor commands and body mechanics. In addition, learning is the only way to acquire motor skills that are defined by social convention, such as writing or dancing.

Most forms of motor learning involve *procedural* or *implicit* learning, so-called because subjects are generally unable to express what it is they have learned. Implicit learning often takes place without consciously thinking about it and can be retained for extended periods of time without practice (see Chapter 66). Typical examples of procedural learning are learning to ride a bicycle or play the piano. In contrast,

explicit or declarative learning involves the acquisition of knowledge that can be expressed in statements about the world and is available to introspection (see Chapter 67). Memorizing the names and routes of the cranial nerves or directions to the local hospital are examples of explicit learning. Declarative memory tends to be easily forgotten, although repeated exposure can lead to long-lasting retention.

Motor learning can occur more or less immediately or require some time. One learns to pick up an object of unknown weight almost immediately and learns to ride a bicycle after a little practice, but mastering the piano requires years. These different timescales may reflect the intrinsic difficulty of the task as well as evolutionary constraints that have to be unlearned to perform the task. For example, piano playing requires learning precise control of the fingers, whereas in normal movements, such as reaching and grasping, individuated finger movements are rare.

Motor Learning Involves Adapting Internal Models for Novel Kinematic and Dynamic Conditions

Sensorimotor transformations have kinematic and dynamic components. Kinematic transformations relate events in different spatial coordinate systems, such as joint angles of the arm and the position of the hand in space. To control a computer mouse, for example, we must learn the kinematic transformation between the handheld mouse and the image of the cursor on the screen. Dynamic transformations relate forces acting at the joints to the motion of the system. We must relate the forces we apply to the mouse to the resulting movement, a transformation that depends on the inertia of the mouse and the friction between the mouse and pad. The kinematics and dynamics of movement vary greatly as we grow and interact with new objects. The brain adapts by reorganizing or adjusting motor commands to generate new actions.

As we saw earlier, we normally move the hand in a straight line to reach an object. Unexpected dynamic interactions may produce curved paths, but subjects learn to anticipate these effects. This learning is conveniently studied by having subjects make pointing movements with an apparatus through which novel forces can be applied to the arm (Figure 33–18A). For example, applying a force that is proportional to the speed of the hand but which acts at right angles to the direction of movement forces the hand into a brief curving movement before reaching the target. Over time the subject adapts to

this perturbation and is able to maintain a straight-line movement (Figure 33–18D).

Subjects might adapt to such a situation in two possible ways. First, they could co-contract the muscles in their arm, thereby stiffening the arm and reducing the impact of the perturbation. Alternatively, they could learn an internal model that compensates for the expected forces, one that uses a new set of motor commands. By examining the subjects' movements after the force is turned off, we can distinguish between these two forms of learning. If the arm simply stiffens, it should continue to move in a straight path. If a new internal model is learned, the new model should compensate for a force that no longer exists, thereby producing a path in the direction opposite from the earlier perturbation. In fact, when the force is turned off, subjects show a large after-effect in the opposite direction, demonstrating that they had learned to compensate for the perturbation (Figure 33–18D).

Although motor learning often takes much practice, once a task is no longer performed de-adaptation is typically quite swift. The context of the movement, that is the sensory inputs associated with a particular task, can be enough to switch behavior. When subjects wear prismatic glasses that rotate visual space, for example, they initially misreach targets but soon learn to reach correctly. After repeated trials the contextual cue of the feel of the glasses, without the prisms in place, is sufficient to switch subjects into behavior suitable with the prisms.

Kinematic and Dynamic Motor Learning Rely on Different Sensory Modalities

Not all sensory modalities are equally important in learning motor tasks. In learning dynamic tasks, proprioception is more important than vision. We normally learn dynamic tasks equally well with or without vision. Patients who have lost proprioception have particular difficulty controlling the dynamic properties of their limbs (Box 33–3) or learning new dynamic tasks without vision.

However, the same patients are easily able to adapt to drastic kinematic changes, such as tracing a drawing while viewing their hand in a mirror. In fact these subjects perform better than normal subjects at such a task, perhaps because they have learned to guide their movements visually and, because of the lack of proprioception, do not experience any conflict between vision and proprioception.

Box 33–3 Proprioception Is Critical for Planning Hand Trajectories and Controlling Dynamics

Sensory neuropathies selectively damage the largediameter sensory fibers in peripheral nerves and dorsal roots that carry most proprioceptive information. Impairments in motor control resulting from loss of proprioception have fascinated neurologists and physiologists for well over a century. Studies of patients with sensory neuropathies provide invaluable insight into the interactions between sensation and movement planning.

As expected, such patients lose joint position sense and vibration and fine tactile sensations (as well as tendon reflexes), but the sense of pain and temperature are fully preserved. These patients are unable to maintain a steady posture, for example while holding a cup or standing, with the eyes closed. Movements also become clumsy, uncoordinated, and inaccurate.

Some recovery of function may occur over many months as the patient learns to use vision as a substitute for proprioception, but this compensation leaves patients completely incapacitated in the dark. Some of this difficulty reflects an inability to detect errors that develop during unseen movements, as occurs if the weight of an object or resistance differs from expectation.

However, this is not all. When the limb cannot be seen, errors in feedforward control of movements

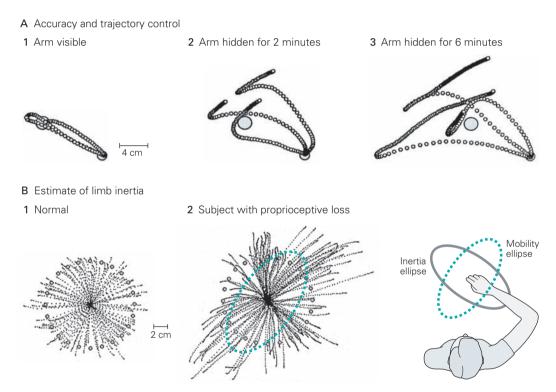

Figure 33–19 Patients lacking proprioception cannot maintain internal models of limb inertia.

A. Accuracy and trajectory control decay rapidly when patients cannot see their limbs. A patient with large-fiber sensory neuropathy, with no sense of position in the arm for several years, moved a mouse-like cursor repeatedly from a starting position to a target displayed on a computer screen in front of her. When the patient was able to see the screen cursor and her hand, movements were straight and reasonably accurate (1). Movements become increasingly curved and inaccurate after vision of her arm was removed for 2 minutes (2) and 6 minutes (3). (Reproduced, with permission, from Ghez, Gordon, and Ghilardi 1995.)

B. A patient without proprioception plans movement without taking account of variations in limb inertia. Patients and normal subjects were instructed to move a finger to 22

targets arranged concentrically. Subjects were prevented from seeing their limb. (1) Movements made by a control subject are straight and evenly distributed throughout the workspace. (2) Movements made by a patient with loss of limb proprioception vary in extent in different directions. The variation in extent is explained by the fact that directional changes in inertia vary with movement direction according to an elliptical contour (inertia ellipse). This means that a constant initial force at the hand will accelerate the limb differently in different directions (mobility ellipse); high acceleration occurs in directions that have low inertia. The mobility computed for the subject's arm plotted over the hand paths shown at left closely matches the variations in movement extent. (Reproduced, with permission, from Gordon, Ghilardi, and Ghez 1995.)

increase over a few minutes and patients become uncertain of where their hands actually move. This is seen clearly in the succession of movements in Figure 33–19A. Movements that are straight and accurate with vision become increasingly curved; instead of stopping, movements drift off to one side or another without the subject's awareness. Thus proprioception is needed to update both inverse models used to control movement and forward models used to estimate body positions resulting from motor commands.

The defects in these models are revealed by examining the errors that occur when the hand moves to targets in different directions (Figure 33–19B). In moving to equidistant targets in many directions, a normal subject moves his hand approximately the same distance in all directions. For patients with proprioceptive loss, the distance moved varies with the direction of movement; movements along the 45-degree axis, perpendicular to the forearm, overshoot the target.

These variations match changes in the inertial resistance of the arm. When the hand moves in the direction

of the forearm (moving both arm and forearm), inertia is two to three times greater than when the hand moves perpendicular to the forearm (moving the forearm alone). Changes in inertia with movement direction fit an elliptical contour. This means that a constant force applied perpendicularly would accelerate the forearm two to three times faster than one applied in the same direction as the forearm.

In all subjects acceleration does indeed vary with movement in different directions, but normal subjects plan movements of shorter duration in directions with lower inertia. In contrast, patients without proprioception are unable to vary the duration (unless they see their limb before moving). Errors therefore reflect the rapid decay of the patient's internal model of limb inertia.

Another form of error occurs in movements with rapid direction reversals. Analyses of the joint torques during these movements show that subjects with intact sensation anticipate intersegmental torques, whereas those without proprioception fail to do so (Figure 33–20).

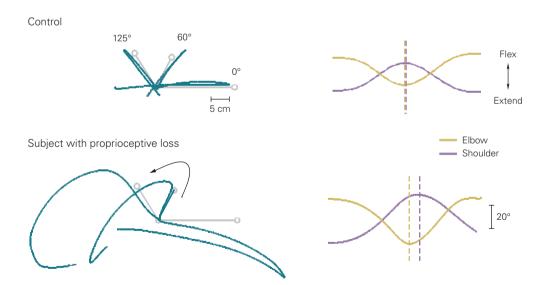

Figure 33–20 Patients lacking proprioception cannot make an accurate movement that requires a rapid reversal in path. In normal subjects the joint angles for the elbow and shoulder show good alignment, leading to an accurate reversal. In subjects who lack proprioceptive

input the timing of the joint reversal is poor, leading to large errors in the path. These patients cannot anticipate and correct for the intersegmental dynamics that occur around the path reversal. (Reproduced, with permission, from Sainburg et al. 1995.)

An Overall View

The primary purpose of the elaborate information processing and storage that occurs in the brain is to enable us to interact with our environment. Our infinitely varied and purposeful motor behaviors are governed by the integrated actions of the brain's several motor systems.

To control action the central nervous system uses a sequence of sensorimotor transformations that convert incoming sensory information into motor outputs. The brain uses internal models at each stage in the sensorimotor transformation. Variability in the inputs and outputs of these transformations and inaccuracies in their representation underlie the errors and variability in movement and lead to the ubiquitous trade-off between speed and accuracy.

The motor systems generate commands using feedforward circuits or error-correcting feedback circuits; most movement involves both types of control. The adverse effects of delays in feedback are reduced through the use of predictive processes.

Finally, motor control circuits are not static but undergo continual modification and recalibration throughout life. Motor learning improves motor control in novel situations, and different forms of sensory information are vital for learning.

The ease with which we conduct ordinary movements masks the true complexity of the control processes involved. Many factors inherent in sensorimotor control are responsible for this complexity, which becomes clearly evident when we try to build machines that can perform human-like control of movement. Although computers can beat grandmasters at chess, no computer can yet control a robot to manipulate a chess piece with the dexterity of a six-year-old child.

An Overall View

NY ACTION—ASCENDING A FLIGHT of stairs, typing on a keyboard, even holding a pose—requires coordinating the movement of body parts. This is accomplished by the interaction of the nervous system with muscle. The role of the nervous system is to activate just those muscles that will exert

the force needed to move in a particular way. This is not a simple task: Not only must the nervous system decide which muscles to activate and how much to activate them in order to move one part of the body, but it must also control muscle forces on other body parts and maintain posture.

This chapter examines how the nervous system controls muscle force and how the force exerted by a limb depends on muscle structure. We also describe how muscle activation differs with different types of movement.

The Motor Unit Is the Elementary Unit of Motor Control

A Motor Unit Consists of a Motor Neuron and Multiple Muscle Fibers

The nervous system controls muscle force with signals sent from motor neurons in the spinal cord to the muscle fibers. A motor neuron and the muscle fibers it innervates are known as a motor unit, the basic functional unit by which the nervous system controls movement, a concept proposed by Charles Sherrington in 1925.

A typical muscle is controlled by a few hundred motor neurons whose cell bodies are clustered in a motor nucleus in the spinal cord or brain stem (Figure 34–1). The axon of each motor neuron exits the spinal cord through the ventral root or through a cranial nerve in the brain stem and runs in a peripheral nerve to the muscle. When the axon reaches the muscle, it branches and innervates from a few to several thousand muscle fibers.

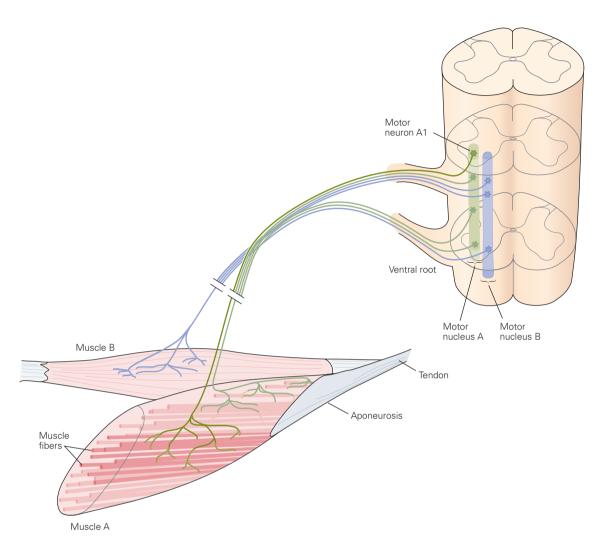

Figure 34–1 A typical muscle consists of many thousands of muscle fibers working in parallel and organized into a smaller number of motor units. A motor unit consists of a motor neuron and the muscle fibers that it innervates, illustrated here by motor neuron A1. The motor neurons innervating one muscle are usually clustered into an elongated motor nucleus that may extend over one to four segments within the ventral spinal cord. The axons from a motor nucleus exit the

spinal cord in several ventral roots and peripheral nerves but are collected into one nerve bundle near the target muscle. In the figure, motor nucleus A includes all those motor neurons innervating muscle A; muscle B is innervated by motor neurons lying in motor nucleus B. The extensively branched dendrites of one motor neuron tend to intermingle with those of motor neurons from other nuclei.

Once synaptic input depolarizes the membrane potential of a motor neuron above threshold, the neuron generates an action potential that is propagated along the axon to its terminal in the muscle. The action potential releases neurotransmitter at the neuromuscular synapse, and this causes an action potential in the sarcolemma of the muscle fibers. A muscle fiber has electrical properties similar to those of a large-diameter, unmyelinated axon, and thus action potentials propagate along the sarcolemma, although more

slowly owing to the fiber's higher capacitance. Because the action potentials in all the muscle fibers of a motor unit occur at approximately the same time, they contribute to extracellular currents that sum to generate a field potential near the active muscle fibers.

Most muscle contractions involve the activation of many motor units, whose currents sum to produce signals detected by electromyography. In many instances the electromyogram (EMG) signal is large and can be easily recorded with electrodes placed on the skin over the muscle. The timing and amplitude of EMG activity, therefore, reflect the activation of muscle fibers by the motor neurons. EMG signals are useful for studying the neural control of movement and for diagnosing pathology (see Chapter 14).

In most mature vertebrate muscles each fiber is innervated by a single motor neuron. The number of muscle fibers innervated by one motor neuron, the *innervation number*, varies with the muscle type and function. In human skeletal muscles it ranges from average values of 5 for an eye muscle to 1,800 for a leg muscle (Table 34–1). Because the innervation number denotes the number of muscle fibers within a motor unit, differences in innervation number indicate differences in the average increment in force that occurs each time a motor unit in the same muscle is activated. Thus the innervation number also indicates the fineness of control of the muscle; the smaller the innervation

Table 34–1 Innervation Numbers in Human Skeletal Muscles

Muscle	Alpha motor axons	Muscle fibers	Innervation number
Biceps brachii	774	580,000	750
Brachioradialis	333	>129,200	>410
Cricothyroid	112	18,550	155
Gastrocnemius (medial)	579	1,042,000	1,800
Interossei dorsales (1)	119	40,500	340
Lumbricales (1)	96	10,269	107
Masseter	1,452	929,000	640
Opponens pollicis	133	79,000	595
Platysma	1,096	27,100	25
Posterior cricoarytenoid	140	16,200	116
Rectus lateralis	4,150	22,000	5
Temporalis	1,331	1,247,000	936
Tensor tympani	146	1,100	8
Tibialis anterior	445	272,850	613
Transverse arytenoid	139	34,470	247

number, the finer the control achieved by varying the number of activated motor units.

Not all motor units in a muscle have the same innervation number. Indeed, the differences can be substantial. For example, motor units of the first dorsal interosseous muscle of the hand have innervation numbers ranging from approximately 21 to 1,770. Consequently, the strongest motor unit in the hand's first dorsal interosseous muscle can exert about the same force as the average motor unit in the leg's medial gastrocnemius muscle.

The muscle fibers of a single motor unit are distributed throughout the muscle and intermingle with fibers innervated by other motor neurons. The muscle fibers of a single motor unit can occupy from 8% to as much as 75% of the volume in a limb muscle, with 2 to 5 muscle fibers per 100 belonging to the same motor unit. Therefore the muscle fibers in a given volume of muscle belong to 20 to 50 different motor units. This distribution changes with age and with some neuromuscular disorders. For example, muscle fibers lose their innervation after the death of a motor neuron and can be reinnervated by collateral sprouts from neighboring axons.

In some muscles the fibers of motor units are confined to discrete compartments that correspond to the regions of the muscle supplied by the primary branches of the muscle nerve. Selective activation of different compartments that exert forces in different directions provides a biomechanical advantage. Branches of the median and ulnar nerves in the forearm, for example, innervate distinct compartments in three multitendon extrinsic hand muscles that enable the fingers to be moved relatively independently. A muscle can therefore consist of several functionally distinct regions.

The Properties of Motor Units Vary

The force exerted by a muscle depends not only on the number of motor units that are activated during a contraction but also on three properties of those motor units: contraction speed, maximal force, and fatigability. These properties are assessed by examining the force exerted by individual motor units in response to variations in the number and rate of evoked action potentials.

The response to a single action potential is known as a *twitch contraction*. The time it takes the twitch to reach its peak force, the *contraction time*, is one measure of the contraction speed of the muscle fibers that comprise a motor unit. Slow-twitch motor units have long contraction times; fast-twitch units have shorter

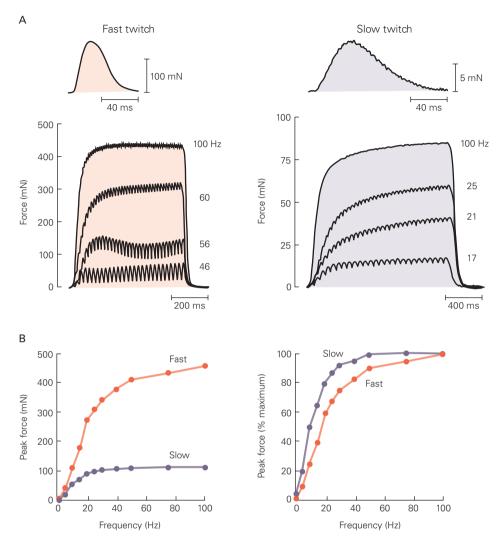

Figure 34–2 The force exerted by a motor unit varies with the rate of the action potentials.

A. Traces show the forces exerted by fast- and slow-twitch motor units in response to a single action potential (top trace) and a series of action potentials (set of four traces below). The time to the peak twitch force, or contraction time, is briefer in the fast-twitch unit. The rates of the action potentials used to evoke the tetanic contractions ranged from 17 to 100 Hz in the slow-twitch unit to 46 to 100 Hz in the fast-twitch unit. The peak force for the 100 Hz tetanus is greater in the fast-twitch unit. Note the different force scales for the two sets of

traces. (Adapted with permission from Botterman et al. 1986; Fuglevand, Macefield, and Bigland-Ritchie 1999; and Macefield, Fuglevand, and Bigland-Ritchie 1996.)

B. Relation between peak force and the rate of action potentials for fast- and slow-twitch motor units. The absolute force (left plot) is greater for the fast-twitch motor unit at all frequencies. At lower stimulus rates (right plot) the force evoked in the slow-twitch motor unit summed to a greater relative force (longer contraction time) than in the fast-twitch motor unit (briefer contraction time).

contraction times. A rapid series of action potentials elicits superimposed twitches known as a *tetanic contraction* or *tetanus*.

The force exerted during a tetanic contraction depends on the extent to which the twitches overlap and summate: The force varies with the contraction time of the motor unit and the rate at which the action potentials are evoked. At lower rates of stimulation the ripples in the tetanus denote the peaks of individual twitches (Figure 34–2A). The peak force achieved during a tetanus varies as a sigmoidal function of action potential rate, with the shape of the curve depending on the contraction time of the motor unit (Figure 34–2B). Maximal force is reached at different

action potential rates for fast-twitch and slow-twitch motor units and is often greater in fast-twitch units.

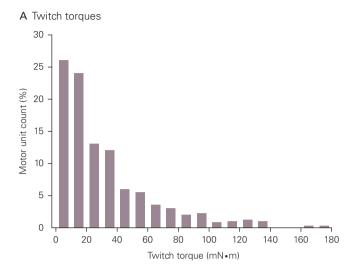

The functional properties of motor units vary across the population and between muscles. At one end of the distribution motor units have long twitch contraction times and produce small forces, but are difficult to fatigue. These motor units are the first activated during a voluntary contraction. In contrast, the last motor units activated have short contraction times, produce large forces, and are easy to fatigue. As observed by Jacques Duchateau and colleagues, most human motor units produce low forces and have intermediate contraction times (Figure 34–3).

Because these contractile properties of a motor unit depend on the characteristics of its muscle fibers, we can distinguish different types of muscle fibers. This distinction stems from structural specializations and differences in the metabolic properties of muscle fibers. All muscle fibers belonging to a motor unit have similar biochemical and histochemical properties.

One commonly used scheme distinguishes muscle fibers by their reactivity to histochemical assays for the enzyme myosin adenosine triphosphatase (ATPase), which is used as an index of contractile speed. Based on histochemical stains for myosin ATPase, it is possible to identify type I and type II muscle fibers. Slow contracting motor units contain type I muscle fibers, and fast contracting units include type II fibers. The type II fibers can be further classified into the least fatigable (type IIa) and most fatigable (type IIb, IIx, or IId). Another commonly used scheme distinguishes muscle fibers on the basis of genetically defined isoforms of the myosin heavy chain. Those in slow contracting motor units express myosin heavy chain-I, those in fast contracting and least fatigable units express myosin heavy chain-IIa, and fibers in fast contracting and most fatigable units express myosin heavy chain-IIb or -IIx. There is a high degree of correspondence between the two classification schemes for muscle fibers.

Physical Activity Can Alter Motor Unit Properties

Alterations in habitual levels of physical activity can influence the three contractile properties of motor units (contraction speed, maximal force, and fatigability). A decrease in muscle activity, such as occurs with aging, bed rest, limb immobilization, or space flight, reduces the maximal capabilities of all three properties. The effects of increased physical activity depend on the intensity and duration of the activity. Brief sets of high-intensity contractions performed a few times each week can increase contraction speed and motor unit force, whereas prolonged periods of low-intensity

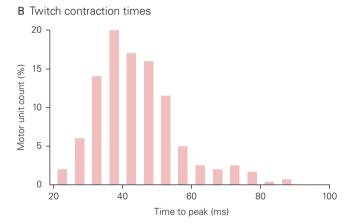

Figure 34–3 Distributions of motor unit properties. (Reproduced, with permission, from Van Cutsem et al. 1997.)

B. Distribution of twitch contraction times for 528 motor units in the tibialis anterior muscle.

contractions can reduce motor unit fatigability. Physical activity regimens that involve such differences are often described as strength training and endurance training, respectively.

Changes in the contractile properties of motor units involve adaptations in the structural specializations and biochemical properties of muscle fibers. The improvement in contraction speed caused by strength training, for example, is associated with an increase in the maximal shortening velocity of a muscle fiber caused by the enhanced capabilities of the myosin molecules in the fiber. Similarly, the increase in maximal force is associated with the enlarged size and increased

intrinsic force capacity of the muscle fibers produced by an increase in the number and density of the contractile proteins.

In contrast, alterations in the fatigability of a muscle fiber can be caused by many different adaptations, such as changes in capillary density, the number of mitochondria, excitation-contraction coupling, and the metabolic capabilities of the muscle fibers. Endurance exercise can promote the biogenesis of mitochondria and enhance the oxidative capacity of a muscle fiber, thereby reducing its fatigability. Although the adaptive capabilities of muscle fibers decline with age, the muscles remain responsive to exercise even at 90 years of age.

Despite the efficacy of strength and endurance training in altering the contractile properties of muscle fibers, these training regimens have little effect on the composition of a muscle's fibers. Although several weeks of exercise can change the proportion of type IIa and IIx fibers, there is no change in the proportion of type I fibers. All fiber types adapt in response to exercise, although to varying extents depending on the type of exercise. For example, strength training of leg muscles for 2 to 3 months can increase the cross-sectional area of type I fibers by 0% to 20% and of type II fibers by 20% to 60%, increase the proportion of type IIa fibers by approximately 10%, and decrease the proportion of type IIx fibers by a similar amount. Furthermore, endurance training may increase the enzyme activities of oxidative metabolic pathways without noticeable changes in the proportions of fiber types, but the relative proportions of type IIa and IIx fibers do change as a function of the duration of each exercise session. Conversely, several weeks of bed rest or limb immobilization do not change the proportions of fiber types in a muscle, but they do decrease the size and intrinsic force capacity of muscle fibers.

Although physical activity has little influence on the proportion of type I fibers in a muscle, more substantial interventions can have an effect. Space flight, for example, exposes muscles to a sustained decrease in gravity, reducing the proportion of type I fibers in leg muscles. A few weeks of continuous electrical stimulation at a low frequency causes a marked increase in the proportion of type I fibers and a substantial decrease in fiber size. Similarly, surgically changing the nerve that innervates a muscle alters the pattern of activation; eventually the muscle exhibits properties similar to those of the muscle that was originally innervated by the transplanted nerve. Connecting a nerve that originally innervated a rapidly contracting leg muscle to a slowly contracting leg muscle, for example, will cause the slower muscle to become more like a faster muscle.

Muscle Force Is Controlled by the Recruitment and Discharge Rate of Motor Units

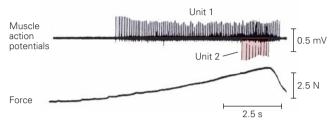

The force exerted by a muscle during a contraction depends on the number of motor units that are activated and the rate at which each of the active motor neurons discharges action potentials. Force is increased during a muscle contraction by the activation of additional motor units, which are recruited progressively from the weakest to the strongest (Figure 34–4). A motor unit's recruitment threshold is the force during the contraction at which the motor unit is activated. Muscle force decreases gradually by terminating the activity of motor units in the reverse order from strongest to weakest.

The order in which motor units are recruited is highly correlated with several indices of motor unit size, including the size of the motor neuron cell bodies, the diameter and conduction velocity of the axons, and the amount of force that the muscle fibers can exert. Because the recruitment threshold of a motor unit depends on the membrane resistance of the motor neuron, which is inversely related to its surface area, a given synaptic current will produce larger changes in the membrane potential of small-diameter motor neurons. Consequently, increases in the net excitatory input to a motor nucleus cause the levels of depolarization to reach threshold in an ascending order of motor neuron size: The smallest motor neuron is recruited first and the largest motor neuron last (Figure 34–5). This effect is known as the size principle of motor neuron recruitment, a principle enunciated by Elwood Henneman in 1957.

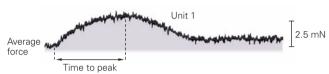

The size principle has two important consequences for the control of movement by the nervous system. First, the sequence of motor-neuron recruitment is determined by spinal mechanisms and not by higher regions of the nervous system. This means that the brain cannot selectively activate specific motor units. Second, motor units are activated in order of increasing fatigability, so the least fatigable motor units available produce the initial force required for a specific task.

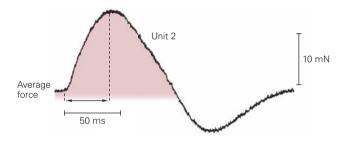

As suggested by Edgar Adrian in the 1920s, the muscle force at which the last motor unit in a motor nucleus is recruited varies between muscles. In some hand muscles all the motor units have been recruited when the force reaches approximately 60% of maximum during a slow muscle contraction. In the biceps brachii, deltoid, and tibialis anterior muscles, recruitment continues up to approximately 85% of the maximal force. However, because the recruitment threshold of motor units decreases with contraction speed, during a rapid contraction most motor units in a muscle are recruited

A Action potentials in two motor units

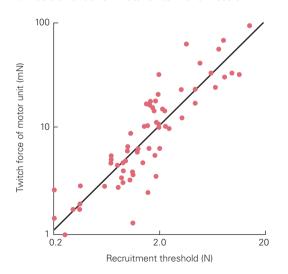

B Force produced by the two units

C Recruitment of 64 motor units in one muscle

with a load of approximately 33% of maximum. Beyond the upper limit of motor unit recruitment, muscle force can still be increased by varying the rate of action potentials in the motor neurons. Below the upper limit of recruitment, the rate of firing can also be varied in addition to increasing the number of active motor units (Figure 34–6). In fact, beneath the upper recruitment limit variation in discharge rate can have the greater influence on muscle force.

The Input-Output Properties of Motor Neurons Are Modified by Input from the Brain Stem

The discharge rate of motor neurons depends on the magnitude of the depolarization generated by excitatory inputs and the intrinsic membrane properties of the motor neurons in the spinal cord. These properties can be profoundly modified by input from monoaminergic neurons in the brain stem. In the absence of this input, the dendrites of motor neurons passively transmit synaptic current to the cell body, resulting in a modest depolarization that immediately ceases when the input stops. Under these conditions the relation between input current and discharge rate is linear over a wide range.

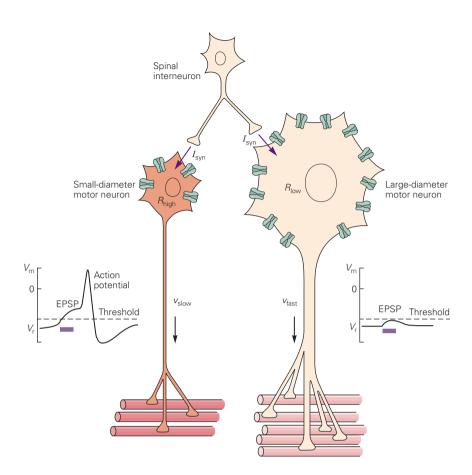

The input–output relation becomes nonlinear, however, when the monoamines serotonin and nore-pinephrine activate L-type Ca²⁺ channels on the dendrites of the motor neurons. The resulting inward Ca²⁺ currents can enhance synaptic currents by five- to tenfold (Figure 34–7). In an active motor neuron this enhanced current can sustain an elevated discharge rate after a brief depolarizing input, a behavior known as *self-sustained firing*. A subsequent brief inhibitory

Figure 34–4 Motor units that exert low forces are recruited before those that exert greater forces. (Adapted, with permission, from Desmedt and Godaux 1977 and from Milner-Brown, Stein, and Yemm 1973.)

A. Action potentials in two motor units were recorded concurrently with a single intramuscular electrode while the subject gradually increased muscle force. Motor unit 1 began discharging action potentials near the beginning of the voluntary contraction, and its discharge rate increased during the contraction. Motor unit 2 began discharging action potentials near the end of the contraction.

- **B.** Average twitch forces for motor units 1 and 2 as extracted with an averaging procedure during the voluntary contraction.
- C. The plot shows the forces at which 64 motor units in a hand muscle of one person were recruited (recruitment threshold) during a voluntary contraction versus the twitch forces of the motor units.

Figure 34-5 The response of a motor neuron to synaptic input depends on its size. Two motor neurons of different sizes have the same resting membrane potential (V_r) and receive the same excitatory synaptic current (I_{syn}) from a spinal interneuron. Because the small motor neuron has a smaller surface area, it has fewer parallel ion channels and therefore a higher resistance (R_{high}). According to Ohm's law (V = IR), I_{syn} in the small neuron produces a large excitatory postsynaptic potential (EPSP) that reaches threshold, resulting in the discharge of an action potential. The small motor neuron has a small-diameter axon that conducts the action potential at a low velocity (v_{slow}) to fewer muscle fibers. In contrast, the large motor neuron has a larger surface area, which results in a lower transmembrane resistance (R_{low}) and a smaller EPSP that does not reach threshold in response to I_{syn} .

input at a low velocity returns the discharge rate to its original value.

Because the properties of motor neurons are strongly influenced by monoamines, the excitability of the pool of motor neurons innervating a single muscle is under control of the brain stem. Moderate monoaminergic input to the motor neurons of slow contracting motor units promotes self-sustained firing. This is probably the source of the sustained force exerted by slower motor units to maintain posture. During sleep,

Figure 34–6 Muscle force can be adjusted by varying the number of active motor units and their discharge rate. A gradual increase and then a decrease in the force (blue line) exerted by the knee extensor muscles involved the concurrent activation of four (out of many) motor units. The muscle force was changed by varying both the number of motor units that were active and the rate at which the motor neurons discharged action potentials. Motor unit 1 was activated when muscle force reached 20% of maximum. Initially the motor neuron discharged action potentials at a rate of 9 Hz. As force increased, the discharge rate increased up to 15 Hz, when both the force and discharge rate declined, and the motor unit was inactivated at 14% of maximal force. Motor units 2, 3, and 4 were activated at greater forces but discharge rate was modulated similarly. (Reproduced, with permission, from Person and Kudina 1972.)

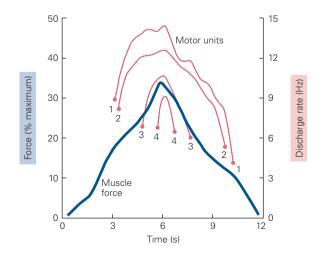

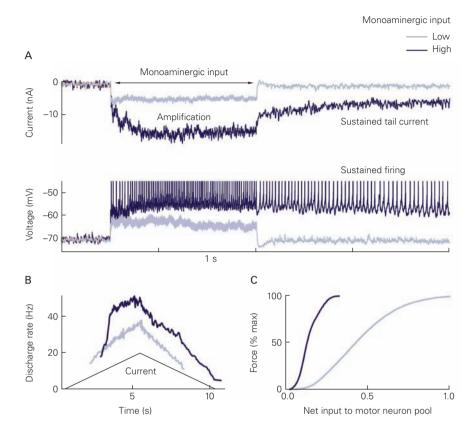

Figure 34–7 Effects of monoaminergic input on motor neurons. (Data from C. J. Heckman.)

A. Membrane currents and potentials in spinal motor neurons of adult cats that were either deeply anesthetized (low monoaminergic drive) or decerebrate (moderate monoaminergic drive). When monoaminergic input is absent or low, a brief excitatory input produces an equally brief synaptic current during voltage clamp (upper record). This current is not sufficient to bring the membrane potential of the cell to threshold for discharging action potentials (lower record). During high levels of monoaminergic input the same brief excitatory input activates a persistent inward current in the dendrites, which amplifies the synaptic current and generates a long-lasting tail current (upper record). This persistent inward current causes a high discharge rate during the input and the tail current sustains the discharge after the input ceases (lower record). A brief inhibition will return the cell to the resting state.

- B. With high levels of monoaminergic input the persistent inward current produces a much higher discharge rate for a given amount of current.
- C. When the entire motor pool innervating a muscle is considered, the monoamine-induced increase in the rate of motor neuron discharge produces a much larger force for a given amount of input and maximal force is achieved with less input to the motor neuron pool.

when monoaminergic drive is withdrawn, excitability decreases, thus helping to ensure a relaxed motor state. Monoaminergic input from the brain stem can adjust the gain of the motor unit pool to suit the demands of different tasks. This flexibility does not compromise the size principle of orderly recruitment because the threshold for activation of the persistent inward currents is lowest in the motor neurons of slower motor units, which are the first recruited even in the absence of monoamines.

Muscle Force Depends on the Structure of Muscle

Muscle force depends not only on the amount of motor unit activity but also on the arrangement of the fibers

in the muscle. Because movement involves the controlled variation of muscle force, the nervous system must take into account the structure of muscle to achieve specific movements.

The Sarcomere Contains the Contractile Proteins

Individual muscles contain thousands of fibers that vary from 1 to 500 mm in length and from 10 to 60 μ m in diameter. The variation in fiber dimensions reflects differences in the quantity of contractile protein. Despite this quantitative variation, the organization of contractile proteins is similar in all muscle fibers. The proteins are arranged in repeating sets of thick and thin filaments, each set known as a *sarcomere* (Figure 34–8). The physiological length of a sarcomere, which is bounded by Z disks, ranges from 1.5 μ m to 3.5 μ m. Sarcomeres

are arranged in series to form a *myofibril*, and the myofibrils are aligned in parallel to form a muscle fiber.

The force that each sarcomere can generate arises from the interaction of the contractile thick and thin filaments. The thick filament consists of a few hundred myosin molecules arranged in a structured sequence. Each myosin molecule comprises paired coiled-coil domains that terminate in two globular heads. The myosin molecules in the two halves of a thick filament point in opposite directions and are progressively displaced so that the heads, which extend away from the filament, protrude from the entire thick filament (Figure 34–8C). To maximize the interaction between the globular heads and the thin filaments, six thin filaments surround each thick filament.

The primary components of the thin filament are two helical strands of fibrous F-actin, each of which contains approximately 200 actin monomers. Superimposed on F-actin are tropomyosin and troponin, proteins that control the interaction between actin and myosin. Tropomyosin consists of two coiled strands that lie in the groove of the F-actin helix; troponin is a small molecular complex that is attached to tropomyosin at regular intervals (Figure 34–8C).

The thin filaments are anchored to the Z disk at each end of the sarcomere, whereas the thick filaments occupy the middle of the sarcomere (Figure 34–8B). This organization accounts for the alternating light and dark bands of striated muscle (Figure 34–8A). The light band contains only thin filaments, whereas the dark band contains both thick and thin filaments. When a muscle is activated, the width of the light band decreases, but the width of the dark band does not change, suggesting that the thick and thin filaments slide relative to one another during a contraction. This led to the *sliding filament hypothesis* of muscle contraction proposed by A. F. Huxley and H. E. Huxley in the 1950s.

The sliding of the thick and thin filaments is triggered by the release of Ca²⁺ within the sarcoplasm of a muscle fiber in response to an action potential at the fiber's membrane, the sarcolemma. Varying the amount of Ca²⁺ in the sarcoplasm controls the interaction between the thick and thin filaments. Under resting conditions the Ca²⁺ concentration in the sarcoplasm is kept low by active pumping of Ca2+ into the sarcoplasmic reticulum, a network of longitudinal tubules and chambers of smooth endoplasmic reticulum (Figure 34-8A). Calcium is stored in the terminal cisternae, which are located next to intracellular extensions of the sarcolemma known as transverse tubules. The transverse tubules, terminal cisternae, and sarcoplasmic reticulum constitute an activation system that transforms an action potential into the sliding of the filaments.

As an action potential propagates along the sarcolemma it invades the transverse tubules and causes the rapid release of Ca²⁺ from the terminal cisternae into the sarcoplasm. Once in the sarcoplasm Ca²⁺ diffuses among the filaments and binds reversibly to troponin, which results in the displacement of the troponintropomyosin complex and activates the sliding of the thick and thin filaments. Because a single action potential is insufficient to release enough Ca²⁺ to bind all available troponin sites in skeletal muscle, the strength of a contraction increases with the action potential rate.

The sliding of the filaments depends on mechanical work performed by the globular heads of myosin, work that uses chemical energy contained in adenosine triphosphate (ATP). The actions of the myosin heads are regulated by the *cross bridge cycle*, a sequence of detachment, activation, and attachment (Figure 34–9). In each cycle a globular head undergoes a displacement of 5 to 10 nm. Contractile activity continues as long as Ca²⁺ and ATP are present in the cytoplasm in sufficient amounts.

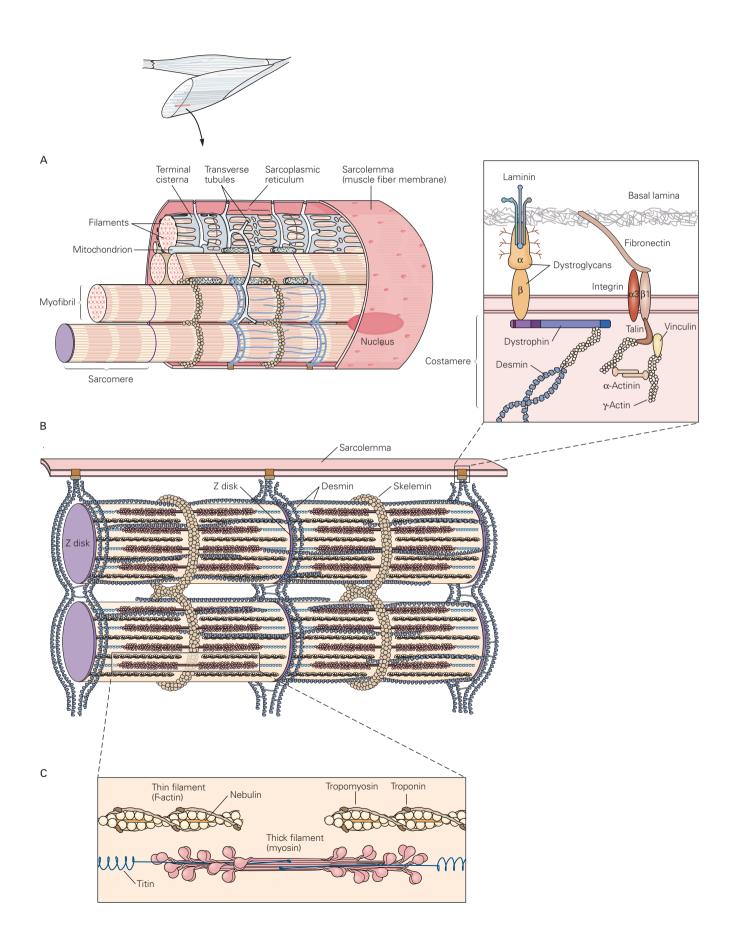

Noncontractile Elements Provide Essential Structural Support

Structural elements of the muscle fiber maintain the alignment of the contractile proteins within the fiber and facilitate the transmission of force from the sarcomeres to the skeleton. A network of proteins (nebulin, titin) maintains the orientation of the thick and thin filaments within the sarcomere, whereas other proteins (desmin, skelemins) constrain the lateral alignment of the myofibrils (Figure 34–8B). These proteins contribute to the elasticity of muscle and maintain the appropriate alignment of cellular structures when the muscle is loaded.

Although some of the force generated by the cross bridges is transmitted along the sarcomeres in series, some travels laterally from the thin filaments to an extracellular matrix that surrounds each muscle fiber, through a group of transmembrane and membrane-associated proteins called a *costamere* (Figure 34–8B). The lateral transmission of force follows two pathways through the costamere, one through a dystrophinglycoprotein complex and the other through vinculin and members of the integrin family. Mutations of genes that encode components of the dystrophin-glycoprotein complex cause muscular dystrophies in humans.

Contractile Force Depends on Muscle Fiber Activation, Length, and Velocity

The force that a muscle fiber can exert depends on the number of cross bridges formed and the force

produced by each cross bridge. These two factors are influenced by the Ca²⁺ concentration in the sarcoplasm, the amount of overlap between the thick and thin filaments, and the velocity with which the thick and thin filaments slide past one another. The influx of Ca²⁺ that activates formation of the cross bridges is transitory because continuous pump activity quickly returns Ca²⁺ to the sarcoplasmic reticulum. The release and reuptake of Ca2+ in response to a single action potential occurs so quickly that only some of the potential cross bridges are formed. This explains why the peak force of a twitch is less than the maximal force of the muscle fiber (see Figure 34-2A). Maximal force can be achieved only with a series of action potentials that sustains the Ca²⁺ concentration in the sarcoplasm, thus maximizing cross bridge formation.

Although Ca²⁺ activates formation of the cross bridges, cross bridges can be formed only when the thick and thin filaments overlap. This overlap varies as the filaments slide relative to one another (Figure 34–10A). At an intermediate sarcomere length (L_0) the amount of overlap between actin and myosin is optimal, and the relative force is maximal. Increases in sarcomere length reduce the overlap between actin and myosin and the force that can be developed. Decreases in sarcomere length cause the thin filaments to overlap, reducing the number of binding sites available to the myosin heads. Although many muscles operate over a narrow range of sarcomere lengths (approximately 94 \pm 13% L_0 , mean \pm SD), among muscles there is considerable diversity in sarcomere lengths during movement.

Because structures that connect the contractile proteins to the skeleton also influence the force that a muscle can exert, muscle force increases with length over its operating range. This property enables muscle to function like a spring and to resist changes in length. Muscle stiffness, which corresponds to the slope of the relation between muscle force and muscle length (N/m), depends on the structure of the muscle. A stiffer muscle, like a stronger spring, is more resistant to changes in length.

Once activated, cross bridges perform work and cause the thick and thin filaments to slide relative to one another. Because of the elasticity of intermediatelength filaments and the extracellular matrix, sarcomeres can shorten even when the length of the muscle fiber is held fixed. The direction and rate of change in sarcomere length depend on the amount of force relative to the magnitude of the load against which the sarcomere acts. Sarcomere length decreases when the force exceeds the load (*shortening contraction*) but increases when the force is less than the load (*lengthening contraction*). The maximal force that a muscle fiber can exert decreases as shortening velocity increases but increases as lengthening velocity increases (Figure 34–10B).

The maximal rate at which a muscle fiber can shorten is limited by the peak rate at which cross bridges can form. The variation in fiber force as contraction velocity changes is largely caused by differences in the average force exerted by each cross bridge. For example, the decrease in force during a shortening contraction is attributable to a reduction in cross bridge displacement during each power stroke and the failure of some myosin heads to find attachment sites. Conversely, the increase in force during a lengthening contraction reflects the stretching of incompletely activated sarcomeres and the more rapid reattachment of cross bridges after they have been pulled apart.

The rate of cross bridge cycling not only depends on contraction velocity, but also on the preceding activity of the muscle. For example, after a brief isometric contraction the rate increases. When a muscle is stretched while in this state, such as would occur

Figure 34–8 (Opposite) The sarcomere is the basic functional unit of muscle. (Adapted, with permission, from Bloom and Fawcett 1975 and from Patel and Lieber 1997.)

A. This section of a muscle fiber shows its anatomical organization. Several myofibrils lie side-by-side in a fiber, and each myofibril is made up of sarcomeres arranged end-to-end and separated by Z disks (see part B). The myofibrils are surrounded by an activation system that includes the transverse tubules, terminal cisternae, and sarcoplasmic reticulum.

B. Sarcomeres are connected to one another and to the muscle fiber membrane by the cytoskeletal lattice. The cytoskeleton influences the length of the contractile thick and thin filaments, maintains the alignment of these filaments within a sarcomere, connects adjacent myofibrils, and transmits force to the

extracellular matrix of connective tissue through costameres. One consequence of this organization is that the force exerted by the contractile elements in a sarcomere can be transmitted along and across sarcomeres (through desmin and skelemin), within and between sarcomeres (through nebulin and titin), and to the costameres. The Z disk is a focal point for many of these connections.

C. The thick and thin filaments consist of various contractile proteins. The thin filament includes polymerized actin along with the regulatory proteins tropomyosin and troponin. The thick filament is an array of myosin molecules; each molecule includes a stem that terminates in a double globular head, which extends away from the filament.

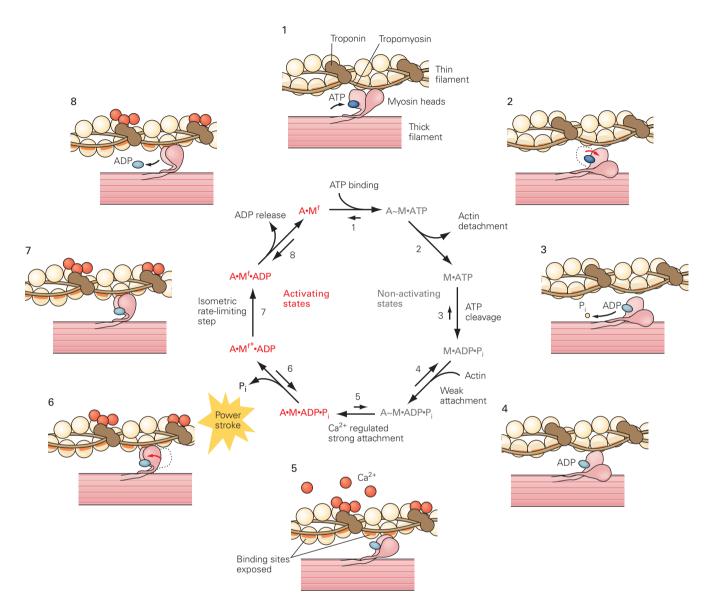

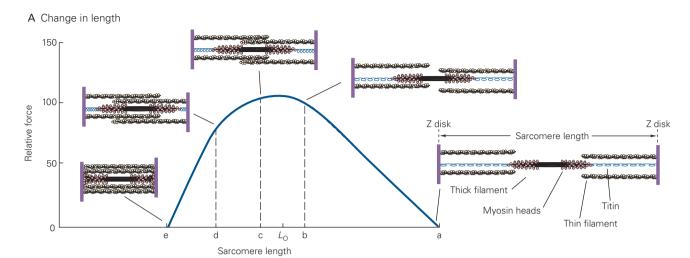

Figure 34–9 The cross bridge cycle. Several nonactivating states are followed by several activating states triggered by Ca²⁺. The cycle begins at the top (step 1) with the binding of adenosine triphosphate (ATP) to the myosin head. The myosin head detaches from actin (step 2), ATP is hydrolyzed to phosphate (P_i) and ADP (step 3), and the myosin becomes weakly bound to actin (step 4). The binding of Ca²⁺ to troponin causes tropomyosin to slide over actin and enables the two

myosin heads to close (step 5). This results in the release of $P_{\rm i}$ and the extension of the myosin neck, the power stroke of the cross bridge cycle (step 6). Each cross bridge exerts a force of about 2 pN during a structural change (step 7) and the release of adenosine diphosphate (ADP) (step 8). (•, strong binding; \sim , weak binding; $M^{\rm f}$, cross bridge force of myosin; and $M^{\rm f*}$, force-bearing state of myosin.) (Adapted, with permission, from Gordon, Regnier, and Homsher 2001.)

during a postural disturbance, muscle stiffness is enhanced, and the muscle is more effective at resisting the change in length. This property is known as *short-range stiffness*. Conversely, the cross bridge cycling rate decreases after shortening contractions, and the muscle does not exhibit short-range stiffness.

Muscle Torque Depends on Musculoskeletal Geometry

The anatomy of a muscle has a pronounced effect on its force capacity, range of motion, and shortening velocity. The anatomical features that influence function include

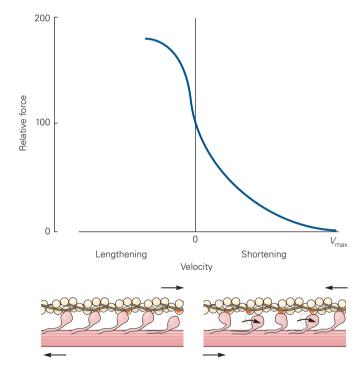

Figure 34–10 Contractile force varies with the change in sarcomere length and velocity.

A. Change in length. At an intermediate sarcomere length, $L_{\rm o}$, the amount of overlap between actin and myosin is optimal and the relative force is maximal. When the sarcomere is stretched beyond the length at which the thick and thin filaments overlap (length a), cross bridges cannot form and no force is exerted. As sarcomere length decreases and the overlap of the thick and thin filaments increases (between lengths a and b), the force increases because the number of cross bridges increases. With further reductions in length (between lengths c and e) the extreme overlap of the thin filaments with each other occludes potential attachment sites and the force decreases.

B. Rate of change. Contractile force varies with the rate of change in sarcomere length. Relative to the force that a

sarcomere can exert during an isometric contraction (zero velocity), the peak force declines as the rate of shortening increases. At the maximal shortening velocity ($V_{\rm max}$) muscle force reaches a minimum. In contrast, when the sarcomere is lengthened while being activated, the peak force increases to values greater than those during an isometric contraction. Shortening causes the myosin heads to spend more time near the end of their power stroke, where they produce less contractile force, and more time detaching, recocking, and reattaching, during which they produce no force. When the muscle is actively lengthened the myosin heads spend more time stretched beyond their angle of attachment and little time unattached because they do not need to be recocked after being pulled away from the actin in this manner.

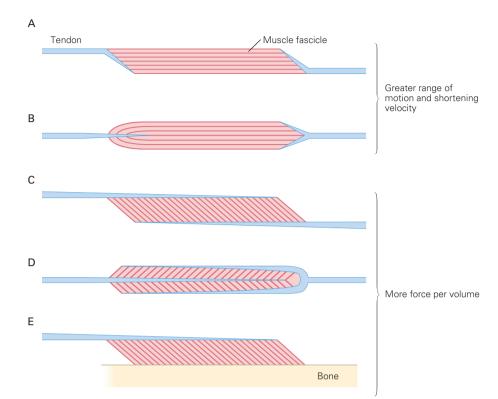

Figure 34–11 Five common arrangements of tendon and muscle. (Reproduced, with permission, from Alexander and Ker 1990.)

the arrangement of the sarcomeres in each muscle fiber, the organization of the muscle fibers within the muscle, and the location of the muscle on the skeleton. These features vary widely among muscles (Figure 34–11).

At the level of the single muscle fiber the number of sarcomeres in series and in parallel can vary. The number of sarcomeres in series determines the length of the myofibril and thus the length of the muscle fiber. Because one sarcomere can shorten by a certain length with a given maximal velocity, both the range of motion and the maximal shortening velocity of a muscle fiber are proportional to the number of sarcomeres in series. The force that a myofibril can exert is equal to the average sarcomere force and is not influenced by the number of sarcomeres in series. The force capacity of a fiber, however, depends on the number of sarcomeres in parallel and hence on the diameter or cross-sectional area of the fiber.

At the level of the muscle, the functional attributes of the fibers are modified by the orientation of the fascicles to the line of pull of the muscle and the length of the fiber relative to the muscle length. In most muscles the fascicles are not parallel to the line of pull but fan out in feather-like (pennate) arrangements (Figure 34–11). The relative orientation, or pennation angle of the fascicles, ranges from 0 degrees (biceps brachii, sartorius) to approximately 30 degrees (soleus). Because

more fibers can fit into a given volume as the pennation angle increases, muscles with large pennation angles typically have more myofibrils in parallel and hence large cross-sectional areas. Given the linear relation between cross-sectional area and maximal force (~0.25 N·mm⁻²), these muscles are capable of a greater maximal force. However, the fibers in pennate muscles are generally short and have a lesser maximal shortening velocity than those in nonpennate muscles.

The functional consequences of this anatomical arrangement can be seen by comparing the contractile properties of two muscles with different numbers of fibers and fiber lengths. If the two muscles have identical fiber lengths, but one has twice as many fibers, the range of motion of the two muscles will be similar because it is a function of fiber length, but the maximal force capacity will vary in proportion to the number of muscle fibers. If the two muscles have identical numbers of fibers but the fibers in one muscle are twice as long, the muscle with the longer fibers will have a greater range of motion and a greater maximal shortening velocity, even though the two muscles have a similar force capacity. Because of this effect, the muscle with longer fibers is able to exert more force and produce more power (the product of force and velocity) at a given absolute shortening velocity (Figure 34–12).

Muscle fiber lengths and cross-sectional areas vary substantially throughout the human body, which suggests that the contractile properties of individual muscles also differ markedly. In the leg, for example, fiber length ranges from 20 mm (soleus) to 460 mm (sartorius), and cross-sectional area ranges from 200 mm² (sartorius) to 5,800 mm² (soleus). Functionally coupled muscles tend to have complementary combinations of these properties. For example, muscles characterized by large pennation angles, large cross-sectional areas, and short fibers (quadriceps femoris) are often functionally coupled with those that have smaller cross-sectional areas and longer fibers (hamstrings).

Movement is the muscle-controlled rotation of adjacent body segments, which means that the capacity of a muscle to contribute to a movement also depends on its location relative to the joint that it spans. The rotary force exerted by a muscle about a joint is referred to as *muscle torque* and is calculated as the product of the muscle force and the *moment arm*, the shortest perpendicular distance from the line of pull of the muscle to the joint's center (Figure 34–13).

The moment arm usually changes as a joint rotates through its range of motion; the amount of change depends on where the muscle is attached to the skeleton relative to the joint. If the force exerted by a muscle remains relatively constant throughout the joint's range of motion, muscle torque varies in direct proportion to the change in the moment arm. For many muscles the moment arm is maximal in the middle of the range of

motion, which usually corresponds to the position of maximal muscle force and hence greatest muscle torque.

Different Movements Require Different Activation Strategies

The human body has approximately 600 muscles, each with a distinct torque profile about one or more joints. To perform a desired movement the nervous system must activate an appropriate combination of muscles with adequate intensity and timing of activity. The activation must be appropriate for the contractile properties and musculoskeletal geometry of many muscles, as well as the mechanical interactions between body segments. As a result of these demands, activation strategies differ with the details of the movement.

Contraction Velocity Can Vary in Magnitude and Direction

Movement speed depends on the contraction velocity of a muscle. The only ways to vary contraction velocity are to alter either the number of motor units recruited or the rates at which they discharge action potentials. The velocity of a contraction can vary in both magnitude and direction (see Figure 34–10B). To control the velocity of a contraction the nervous system must scale the magnitude of the net muscle torque relative to the load torque, which includes both the weight of the body segment and any load applied externally to the body.

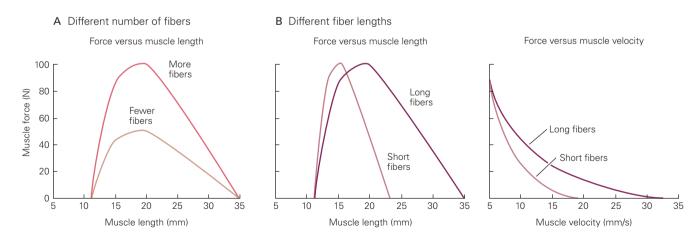

Figure 34–12 Muscle dimensions influence the peak force and maximal shortening velocity. (Reproduced, with permission, from Lieber and Fridén 2000.)

A. Muscle force at various muscle lengths for two muscles with similar fiber lengths but different numbers of muscle fibers (different cross-sectional area). The muscle with twice as many fibers exerts greater force.

B. Muscle force at various muscle lengths for two muscles with the same cross-sectional area but different fiber lengths. The muscle with longer fibers (about twice as long as those of the other muscle) has an increased range of motion (left plot). It also has a greater maximal shortening velocity and exerts greater force at a given absolute velocity (right plot).

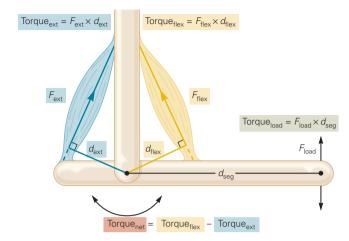

Figure 34–13 Muscle torque varies over a joint's range of motion. A muscle exerts a torque about a joint that is the product of its contractile force (F) and its moment arm at the joint (d). The moment arm is the shortest perpendicular distance from the line of pull of the muscle to the joint's center of rotation. Because the moment arm changes when the joint rotates, muscle torque varies with angular displacement about the joint. The net torque about a joint, which determines the mechanical action, is the difference in the torques exerted by opposing muscles, such as extensors (ext) and flexors (flex). Similarly, a force applied to the limb (F_{load}) will exert a torque about the joint that depends on F_{load} and its distance from the joint (d_{seq}).

When muscle torque exceeds load torque, the muscle shortens as it performs a shortening contraction. When muscle torque is less than load torque, the muscle lengthens as it performs a lengthening contraction. For the example shown in Figure 34–13, the load is lifted with a shortening contraction of the flexor and lowered with a lengthening contraction. Both types of contractions are common in daily activities.

Shortening and lengthening contractions are not simply the result of adjusting motor unit activity so that the net muscle torque is greater or less than the load torque. When the task involves lifting a load with a prescribed trajectory, activation of the motor units must be aligned so that the summed rise times match the desired trajectory during the shortening contraction, whereas the lengthening contraction requires that the summed decay times be matched. The nervous system accomplishes this by varying the descending input and sensory feedback during the two contractions. Because of these differences, some people, such as older adults and persons performing rehabilitation exercises after an orthopedic procedure, have greater difficulty performing lengthening contractions.

The amount of motor-unit activity relative to the load also influences the contraction velocity. This effect

depends on both the number of motor units recruited and the maximal rates at which the motor units can discharge action potentials. For example, the maximal rate of increase in muscle torque during a submaximal contraction increases after several weeks of physical training and is associated with a marked increase in the initial discharge rates of the activated motor units. Physical training increases the rate at which motor units can discharge trains of action potentials, an effect that can be mimicked by the rapid injection of current into a motor neuron. Changes in the maximal shortening velocity of a muscle after a change in the habitual level of physical activity are the result, at least partly, of factors that influence the ability of motor units to discharge action potentials at high rates.

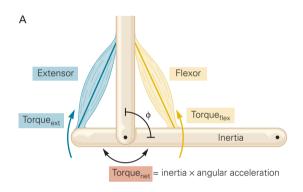

Movements Involve the Coordination of Many Muscles

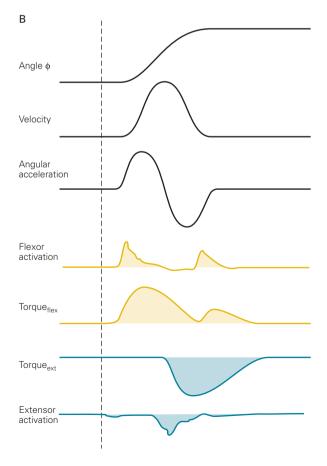

To achieve a prescribed trajectory the nervous system must activate not only the muscles that produce the desired displacement but also muscles that prevent unintended actions. For example, the elbow flexor muscles are used to rapidly rotate the forearm about the elbow joint. But unless the muscles that cross the wrist are also activated to stabilize the wrist joint, rotation of the forearm would cause the hand to flail about the wrist joint.

In the simplest case muscles span a single joint and cause the attached body segments to accelerate about a single axis of rotation (Figure 34–14A). Because muscles can exert only a pulling force, motion about a single axis of rotation requires at least two muscles or groups of muscles. Thus, the flexion-extension motion about the knee joint involves the hamstring muscles to exert force in the direction of flexion and the quadriceps to exert force in the direction of extension.

However, many muscles attach to the skeleton slightly off center and can cause movement about more than one axis of rotation. If one of the actions is not required, the nervous system must activate other muscles to control the unwanted movement. For example, activation of the radial flexor muscle of the wrist can cause the wrist to flex and abduct. If the intended action is only wrist flexion, then the abduction action must be opposed by another muscle, such as the ulnar flexor muscle, which causes wrist flexion and adduction. Depending on the geometry of the articulating surfaces and the attachment sites of the muscles, the multiple muscles that span a joint are capable of producing movements about one to three axes of rotation. Furthermore, some structures can be displaced linearly (eg, the scapula on the trunk), adding to the degrees of freedom about a joint.

This organization enhances the flexibility of the skeletal motor system, for the same movement can be achieved by activating different combinations of muscles. However, this additional flexibility comes with a cost in the corresponding variation in the unwanted actions that must be controlled. A solution used by the nervous system is to organize relations among selected muscles to produce specific actions. A particular balance of muscle activations that changes over time is known as a *muscle synergy*, and movement is produced through

the coordinated activation of these synergies. For example, electromyographic recordings suggest that a range of human movements, such as grasping objects with the hand, reaching and pointing in different directions, and walking and running at several speeds, are controlled by approximately five muscle synergies.

The number of muscles that participate in a movement also varies with the speed of the movement. For example, slow lifting of the load shown in Figure 34–13 requires only that the muscle torque slightly exceed the load torque, and thus only the flexor muscle is activated. This strategy is used when lifting a handheld weight with the elbow flexor muscles. In contrast, to perform this movement rapidly with an abrupt termination, both the flexor and extensor muscles must be activated. First the flexor muscle is activated to accelerate the limb in the direction of flexion, followed by activation of the extensor muscle to accelerate the limb in the direction of extension, and finally a burst of activity by the flexor muscle to reduce the angular momentum of the limb and the handheld weight in the direction of flexion so that it arrives at the desired joint angle (Figure 34–14B). The amount of extensor activity increases with the speed of the movement.

Increases in movement speed introduce another factor that the nervous system must control: unwanted accelerations in other body segments. Because body segments are interconnected, motion in one segment can induce motion in another. At the beginning of the swing phase in running, for example, the hip flexor muscles are activated and accelerate the thigh in a forward direction (Figure 34–15A). The motion of the thigh causes the lower leg to rotate backward about the knee joint. To control the backward displacement

Figure 34–14 Muscle torque must overcome inertia when a movement is started and stopped.

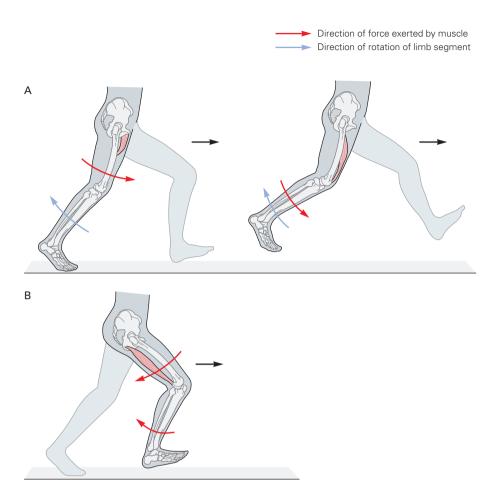

A. According to Newton's law of acceleration (force = mass \times acceleration), force is required to change the velocity of a mass. Muscles exert a torque to accelerate the inertial mass of the skeletal segment around a joint. For angular motion, Newton's law is written as torque = rotational inertia \times angular acceleration.

B. The angular velocity for movement of a limb from one position to another has a bell-shaped profile reflecting Newton's law of acceleration. Acceleration in one direction is followed by acceleration in the opposite direction—the flexor and extensor muscles are activated in succession. The records here show the activation profiles and associated muscle torques for an elbow flexion movement. Because contractile force decays relatively slowly, the flexor muscle is usually activated a second time to counter the prolonged acceleration generated by the extensor muscle and to stop the limb exactly on target.

Figure 34–15 A single muscle can influence the motion about many joints.

A. Muscles that cross one joint can accelerate an adjacent body segment. For example, at the beginning of the swing phase while running, the hip flexor muscles are activated to accelerate the thigh forward (red arrow). This action causes the lower leg to rotate backward (blue arrow) and the knee joint to flex. To control the knee joint flexion during the first part of the swing phase, the knee extensor muscles are activated and undergo a lengthening contraction to accelerate the lower leg forward (red arrow) while it continues to rotate backward (blue arrow).

B. Many muscles cross more than one joint to exert an effect on more than one body segment. For example, the hamstring muscles of the leg accelerate the hip in the direction of extension and the knee in the direction of flexion (red arrows). At the end of the swing phase during running, the hamstring muscles are activated and undergo lengthening contractions to control the forward rotation of the leg (hip flexion and knee extension). This strategy is more economical than activating individual muscles at the hip and knee joints to control the forward rotation of the leg.

of the lower leg, the quadriceps muscles are activated to accelerate the lower leg in the forward direction. As the lower leg rotates backward, the quadriceps muscles perform a lengthening contraction that becomes a shortening contraction to rotate the lower leg forward in the middle of the swing phase.

Muscles that span more than one joint can be used to control the motion-dependent interactions between body segments. At the end of the swing phase in running, activation of the hamstring muscles causes both the thigh and lower leg to accelerate backward (Figure 34–15B). If a hip extensor muscle was used to accelerate the thigh backward instead of the hamstring muscles, the lower leg would accelerate forward, requiring activation of a knee flexor muscle to control the unwanted motion so that the foot could be placed on the ground. Use of the two-joint hamstring muscles is a more economical strategy, but one that can subject the hamstrings to high stresses during fast movements, such as sprinting. The control of such motion-dependent interactions

often involves lengthening contractions, which maximize muscle stiffness and the ability of muscle to resist changes in length.

For most movements the nervous system must establish rigid connections between some body segments for two reasons. First, as expressed in Newton's law of action and reaction, a reaction force must provide a foundation for the acceleration of a body segment. For example, in a reaching movement performed by a person standing upright, the ground must provide a reaction force against the feet. The muscle actions that produce the arm movement exert forces that are transmitted through the body to the feet and are opposed by the ground. Different substrates provide different amounts of reaction force, so ice or sand substantially alter movement capabilities.

Second, uncertain conditions are usually accommodated by stiffening the joints through concurrent activation of the muscles that produce force in opposite directions. Coactivation of opposing muscles

occurs often when a support surface is unsteady, when the body might experience an unexpected perturbation, or when lifting a heavy load. Because coactivation increases the energetic cost of performing a task, one characteristic of skilled performance is the ability to accomplish a task with minimal activation of muscles that span associated joints.

Muscle Work Depends on the Pattern of Activation

Limb muscles in healthy young adults are active 10% to 20% of the time during waking hours. For much of this time the muscles perform constant-length (*isometric*) contractions to maintain a variety of static body postures. In contrast, muscle length has to change during a

movement so that the muscle can perform work to displace body segments. A muscle performs positive work and produces power during a shortening contraction, whereas it performs negative work and absorbs power during a lengthening contraction. The capacity of muscle to do positive work establishes performance capabilities, such as the maximal height that can be jumped.

The nervous system enhances the work capacity of muscle by commanding a brief period of negative work before positive work. This activation sequence, the *stretch-shorten cycle*, occurs in many movements. When a person jumps in place on two feet, for example, the support phase involves an initial stretch and subsequent shortening of the ankle extensor and knee extensor muscles (Figure 34–16A). The forces in the Achilles

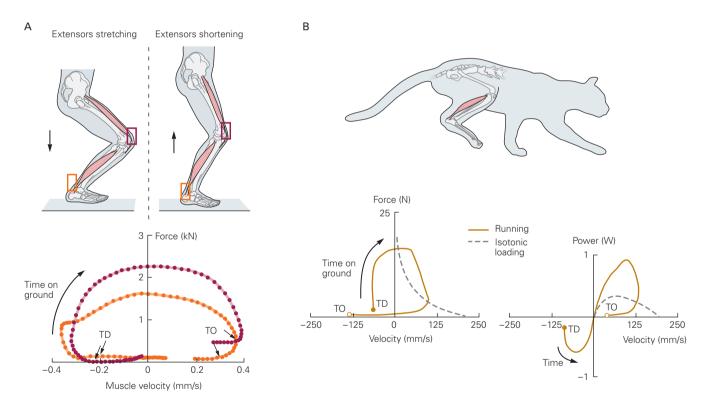

Figure 34–16 An initial phase of negative work enhances subsequent positive work performed by the muscle. (Reproduced, with permission, from Finni, Komi, and Lepola 2000 and from Gregor et al. 1988.)

A. The force in the Achilles tendon and patellar tendon vary during the ground-contact phase of two-legged hopping. The feet contact the ground at touchdown (TD) and leave the ground at toe-off (TO). For approximately the first half of the movement the quadriceps and triceps surae muscles lengthen, performing negative work (negative velocity). The muscles perform positive work when they shorten (positive velocity).

B. The force exerted by the soleus muscle of a cat running at moderate speed varies from the instant the paw touches the

ground (TD) until it leaves the ground (TO). The force exerted by the muscle during the shortening contraction is greater than the peak forces measured when the muscle contracts maximally against various constant loads (isotonic loading). Negative velocity reflects a lengthening contraction in the soleus muscle. The power produced by the soleus muscle of the cat during running is greater than that produced in an isolated-muscle experiment (dashed line). The phase of negative power corresponds to the lengthening contraction just after the paw is placed on the ground (TD), when the muscle performs negative work.

and patellar tendons increase during the stretch and reach a maximum at the onset of the shortening phase. As a result, the muscles can perform more positive work and produce more power during the shortening contraction (Figure 34–16B).

Although negative work involves an increase in the length of the muscle, the length of the fascicles in the muscle often remains relatively constant, which indicates that the connective-tissue structures are stretched prior to the shortening contraction. Thus the capacity of the muscle to perform more positive work comes from strain energy that can be stored in the tendon during the stretch phase and released during the subsequent shortening phase. The ability of a muscle to benefit from this strategy depends on its morphological characteristics and is greatest in muscles with long tendons.

An Overall View

Movement involves the coordinated interaction of the nervous system and muscle. The basic functional unit of motor control is the motor unit, which consists of a motor neuron and the muscle fibers that it innervates. The force exerted by a muscle depends in part on the number and properties of the motor units that are activated. These properties include contraction speed, maximal force, and fatigability, all of which can be altered by physical activity. The rate of firing in each active motor neuron is also a factor in muscle force. Motor units tend to be activated in a stereotypical order that is highly correlated with motor-neuron size.

Muscle force depends not only on the characteristics of motor-unit activity, but also on the arrangement of the muscle fibers. The sarcomere is the smallest element of muscle to include a complete set of contractile proteins. A transient connection between the contractile proteins myosin and actin, known as the cross bridge cycle, enables muscle to exert a force. The organization of the sarcomeres within a muscle varies substantially and has a major effect on the contractile properties of the muscle.

For a given arrangement of sarcomeres, the force a muscle can exert depends on the activation of the cross bridges by Ca²⁺, the amount of overlap between the thick and thin filaments, and the velocity of the moving filaments. The functional capability of a muscle depends on the torque that it can exert, which is influenced both by its contractile properties and by the location of its attachments on the skeleton relative to the joint that it spans.

To perform a movement the nervous system activates multiple muscles and controls the torque exerted about the involved joints. The nervous system can vary the magnitude and direction of a movement by altering the amount of motor unit activity, and hence muscle torque, relative to the load acting on the body. Increases in movement speed, however, enhance motion-dependent interactions between body segments, producing unwanted accelerations that must be controlled by the nervous system. Furthermore, the nervous system must coordinate the activity of multiple muscles to provide a mechanical link between moving body segments and the required support from the surroundings. The patterns of muscle activity vary substantially between movements and often include strategies that augment the work capacity of muscles.

Proprioceptive Reflexes Play an Important Role in Regulating Both Voluntary and Automatic Movements

Reflexes Involving Limb Muscles Are Mediated Through Spinal and Supraspinal Pathways

Stretch Reflexes Reinforce Central Commands for Movements

Damage to the Central Nervous System Produces Characteristic Alterations in Reflex Response and Muscle Tone

Interruption of Descending Pathways to the Spinal Cord Frequently Produces Spasticity

Transection of the Spinal Cord in Humans Leads to a Period of Spinal Shock Followed by Hyperreflexia

An Overall View

URING PURPOSEFUL MOVEMENTS the central nervous system uses information from a vast array of sensory receptors to ensure that the pattern of muscle activity suits the purpose. Without this sensory information movements tend to be imprecise, and tasks requiring fine coordination in the hands, such as buttoning one's shirt, are impossible.

Charles Sherrington was among the first to recognize the importance of sensory information in regulating movements. In 1906 he proposed that simple reflexes—stereotyped movements elicited by activation of receptors in skin or muscle—are the basic units for movement. He further posited that complex sequences of movements can be produced by combining simple reflexes. This view guided motor physiology for much of the 20th century.

The view that reflexes are automatic, stereotyped movements in response to stimulation of peripheral receptors arose primarily from laboratory studies of reflexes in animals with central nervous system lesions. Once investigators began to measure reflexes in intact animals engaged in normal behavior, ideas about reflexes changed. We now know that reflexes are flexible, that under normal conditions they can be adapted to a task. The prevalent view today is that reflexes are integrated by centrally generated motor commands into complex adaptive movements.

In this chapter we consider the principles underlying the organization and function of reflexes, focusing on spinal reflexes. The sensory stimuli for spinal reflexes arise from receptors in muscles, joints, and skin, and the neural circuitry responsible for the motor response is entirely contained within the spinal cord.

Reflexes Are Adaptable to Particular Motor Tasks

A good example of the adaptability of reflexes is how certain reflexes change in response to stretching the wrist muscles. When a person is kneeling or standing the stretched muscles contract, but muscles in other limbs also contract to prevent a loss of balance. Interestingly, the reflex response of the elbow extensor of the opposite arm depends on how that arm is being used.

If the arm is used to stabilize the body by holding the edge of a table, a large excitatory response in the elbow extensor muscle resists the forward sway of the body. If the arm is instead holding an unsteady object such as a cup of tea, reflex inhibition of the elbow extensors prevents movement of the cup (Figure 35–1A).

Another example of adaptability is the reflex of finger and thumb flexor muscles in response to stretching thumb muscles. If a subject rhythmically taps the tips of the index finger and thumb to each other, and flexion of the thumb is resisted, a short-latency reflex response is produced in *both* the finger and thumb flexor muscles. As a result, the reflex in the finger flexor muscle produces a larger flexion movement of the finger to compensate for the reduced flexion of the thumb and ensure the performance of the intended task (Figure 35–1B). If the subject is simply making rhythmic thumb movements, a reflex response is produced only in the thumb flexor muscle.

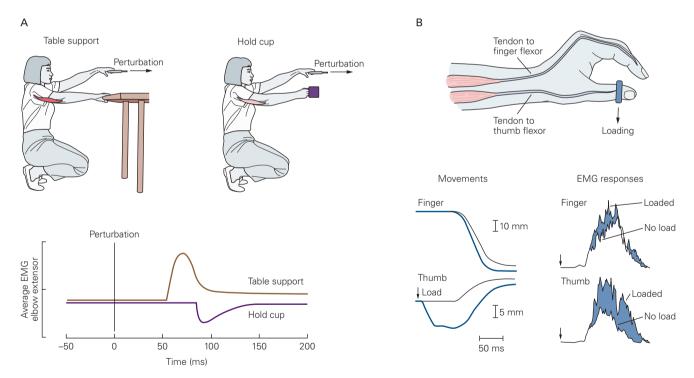

Figure 35–1 Reflex responses are often complex and can change depending on the task.

A. Perturbation of one arm causes an excitatory reflex response in the contralateral elbow extensor muscle when the contralateral limb is used to prevent the body from moving forward by grasping a table. The same stimulus produces an inhibitory response in the muscle when the contralateral hand holds a filled cup. (Adapted, with permission, from Marsden et al. 1981.)

B. Loading the thumb during a rhythmic sequence of finger-to-thumb pinching movements produces a reflex response in the finger muscle as well as the thumb muscle. The additional movement of the finger ensures that the pinching movement remains accurate. The blue area in the electromyogram (EMG) records indicates the reflex response. (Adapted, with permission, from Cole et al. 1984.)

A third example of adaptability is the conditioning of the flexion-withdrawal reflex. Flexion-withdrawal can be associated with an auditory tone by classical conditioning (see Chapter 65). A subject is asked to place the palmar surface of an index finger on an electrode. A mild electrical shock is then paired with an audible tone. As expected, after only a few pairings the tone alone will elicit the withdrawal reflex. What exactly has been conditioned? Is it the contraction of a fixed group of muscles or the behavioral *act* that withdraws the finger from the noxious stimulus?

This question can be answered by having the subject turn his or her hands over after conditioning is complete, so that now the dorsal surface of the finger is in contact with the electrode. Most subjects will withdraw their fingers from the electrode when the tone is played, even though this means that the opposite muscles now contract. Thus, the conditioned response is not merely a stereotyped set of muscle contractions but the elicitation of an appropriate behavior.

Three important principles are illustrated by these examples. First, neural signaling in reflex pathways is adjusted according to the motor task. The state of the reflex pathways for any task is referred to as the *functional set*. Exactly how a functional set is established for most motor tasks is largely unknown, and unraveling the underlying mechanisms is one of the challenging areas of contemporary research on motor systems. Second, sensory input from a localized source generally produces coordinated reflex responses in several muscles at once, some of which may be distant from the stimulus. Third, supraspinal centers play an important role in modulating and adapting spinal reflexes, even to the extent of reversing movements when appropriate.

To understand the neural basis for reflexes and how they are modified for a particular task, we must first have a thorough knowledge of how reflex pathways are organized in the spinal cord. Although under normal conditions descending central commands directly shape spinal reflexes, many qualitative features of spinal reflexes are maintained after complete transection of the spinal cord, a condition that isolates the spinal circuits from the brain.

Spinal Reflexes Produce Coordinated Patterns of Muscle Contraction

Cutaneous Reflexes Produce Complex Movements That Serve Protective and Postural Functions

A familiar example of a spinal reflex is the flexionwithdrawal reflex, in which a limb is quickly withdrawn from a painful stimulus. Flexion-withdrawal is a protective reflex in which a discrete stimulus causes all the flexor muscles in that limb to contract coordinately. We know that this is a spinal reflex because it persists after complete transection of the spinal cord.

The sensory signal activates divergent polysynaptic reflex pathways. One excites motor neurons that innervate flexor muscles of the stimulated limb, whereas another inhibits motor neurons that innervate the limb's extensor muscles (Figure 35–2A). Excitation of one group of muscles and inhibition of their antagonists—those that act in the opposite direction—is what Sherrington called *reciprocal innervation*, a key principle of motor organization that is discussed later in this chapter.

The reflex can produce an opposite effect in the contralateral limb, that is, excitation of extensor motor neurons and inhibition of flexor motor neurons. This *crossed-extension reflex* serves to enhance postural support during withdrawal of a foot from a painful stimulus. Activation of the extensor muscles in the opposite leg counteracts the increased load caused by lifting the stimulated limb. Thus, flexion-withdrawal is a complete, albeit simple, motor act.

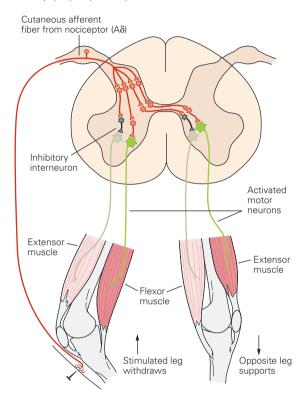

Although flexion reflexes are relatively stereotyped, both the spatial extent and the force of muscle contraction depend on stimulus intensity. Touching a stove that is slightly hot may produce moderately fast withdrawal only at the wrist and elbow, whereas touching a very hot stove invariably leads to a forceful contraction at all joints, leading to a rapid withdrawal of the entire limb. The duration of the reflex usually increases with stimulus intensity, and the contractions produced in a flexion reflex always outlast the stimulus.

Because of the similarity of the flexion-withdrawal reflex to stepping, it was once thought that the flexion reflex is important in producing contractions of flexor muscles during walking. We now know, however, that a major component of the neural control system for walking is a set of intrinsic spinal circuits that do not require sensory stimuli (see Chapter 36). Nevertheless, in mammals the intrinsic spinal circuits that control walking share many of the interneurons that are involved in flexion reflexes.

The Stretch Reflex Resists the Lengthening of a Muscle

Perhaps the most important—certainly the most studied—spinal reflex is the *stretch reflex*, a lengthening contraction of a muscle. Stretch reflexes were originally thought to be an intrinsic property of muscles. But early in the last century Liddell and Sherrington showed that they could be abolished by cutting either the dorsal or the ventral root, thus establishing that

A Polysynaptic pathways (flexion reflex)

B Monosynaptic pathways (stretch reflex)

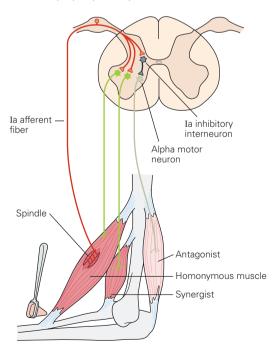

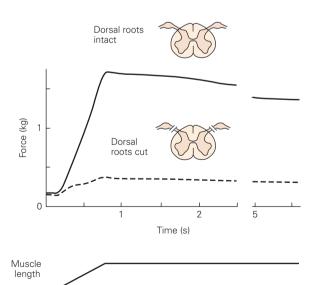

Figure 35–2 Spinal reflexes involve coordinated contractions of numerous muscles in the limbs.

A. Polysynaptic pathways in the spinal cord mediate flexion and crossed-extension reflexes. One excitatory pathway activates motor neurons that innervate ipsilateral flexor muscles, which withdraw the limb from noxious stimuli. Another pathway simultaneously excites motor neurons that innervate contralateral extensor muscles, providing support during withdrawal of the limb. Inhibitory interneurons ensure that the motor neurons supplying antagonist muscles are inactive during the reflex response. (Adapted, with permission, from Schmidt 1983.)

B. Monosynaptic pathways mediate stretch reflexes. Afferent axons from muscle spindles make excitatory connections on two sets of motor neurons: alpha motor neurons that innervate the same (homonymous) muscle from which they arise and motor neurons that innervate synergist muscles. They also act through interneurons to inhibit the motor neurons that innervate antagonist muscles. When a muscle is stretched by a tap with a reflex hammer, the firing rate in the afferent fiber from the spindle increases. This leads to contraction of the same muscle and its synergists and relaxation of the antagonist. The reflex therefore tends to counteract the stretch. enhancing the spring-like properties of the muscles. The records on the right demonstrate the reflex nature of contractions produced by muscle stretch in a decerebrate cat. When an extensor muscle is stretched it normally produces a large force, but it produces a very small force (dashed line) after the sensory afferents in the dorsal roots have been severed. (Adapted, with permission, from Liddell and Sherrington 1924.)

these reflexes require sensory input from muscle to spinal cord and a return path to muscle (Figure 35–2B).

We now know that the receptor that senses the change of length is the muscle spindle (Box 35–1) and that the type Ia axon from this receptor makes direct

excitatory connections with motor neurons. (The classification and nomenclature of sensory fibers from muscle are discussed in Box 35–2.) The afferent axon also connects to interneurons that inhibit the motor neurons that innervate antagonist muscles, another

Box 35–1 Muscle Spindles

Muscle spindles are small encapsulated sensory receptors that have a spindle-like or fusiform shape and are located within the fleshy part of a muscle. Their main function is to signal changes in the length of the muscle within which they reside. Changes in length of muscles are closely associated with changes in the angles of the joints that the muscles cross. Thus muscle spindles are used by the central nervous system to sense relative positions of the body segments.

Each spindle has three main components: (1) a group of specialized *intrafusal* muscle fibers with central regions that are noncontractile; (2) sensory fibers that terminate in the noncontractile central regions of the intrafusal fibers; and (3) motor axons that terminate in the polar contractile regions of the intrafusal fibers (Figure 35–3A).

When the intrafusal fibers are stretched, often referred to as "loading the spindle," the sensory nerve endings are also stretched and increase their firing rate. Because muscle spindles are arranged in parallel with the *extrafusal* muscle fibers that make up the main body of the muscle, the intrafusal fibers change in length as the whole muscle changes. Thus, when a muscle is stretched, activity in the sensory endings of muscle spindles increases. When a muscle shortens, the spindle is unloaded and the activity decreases.

The intrafusal muscle fibers are innervated by *gamma* motor neurons, which have small-diameter myelinated axons, whereas the extrafusal muscle fibers are innervated by *alpha* motor neurons, with large-diameter myelinated axons. Activation of gamma motor neurons causes shortening of the polar regions of the intrafusal fibers. This in turn stretches the central region from both ends, leading to an increase in firing rate of the sensory endings or to a greater likelihood that the sensory endings will fire in response to stretch of the muscle. Thus the gamma motor neurons adjust the sensitivity of the muscle spindles. Contraction of the intrafusal muscle fibers does not contribute significantly to the force of muscle contraction.

The structure and functional behavior of muscle spindles is considerably more complex than this simple description implies. When a muscle is stretched the change in length has two phases: a dynamic phase, the period during which length is changing, and a static or steady-state phase, when the muscle has stabilized at a new length. Structural specializations within each component of the muscle spindles allow spindle afferents to signal aspects of each phase separately.

There are two types of intrafusal muscle fibers: nuclear bag fibers and nuclear chain fibers. The bag fibers can be divided into two groups, dynamic and static. A typical spindle has two or three bag fibers and a variable number of chain fibers, usually about five. Furthermore, the intrafusal fibers receive two types of sensory endings. A single Ia (large diameter) axon spirals around the central region of all intrafusal muscle fibers and serves as the primary sensory ending (Figure 35–3B). A variable number of type II (medium diameter) axons, located adjacent to the central regions of the static bag and chain fibers, serve as secondary sensory endings.

The gamma motor neurons can also be divided into two classes: Dynamic gamma motor neurons innervate the dynamic bag fibers, whereas the static gamma motor neurons innervate the static bag fibers and the chain fibers.

This duality of structure is reflected in a duality of function. The tonic discharge of both primary and secondary sensory endings signals the steady-state length of the muscle. The primary sensory endings are, in addition, highly sensitive to the velocity of stretch, allowing them to provide information about the speed of movements. Because they are highly sensitive to small changes, the primary endings rapidly provide information about sudden unexpected changes in length, which can be used to generate quick corrective reactions.

Increases in the firing rate of dynamic gamma motor neurons increase the dynamic sensitivity of primary sensory endings but have no influence on secondary sensory endings. Increases in the firing rate of static gamma motor neurons increase the tonic level of activity in both primary and secondary sensory endings, decrease the dynamic sensitivity of primary endings (Figure 35–3C), and can prevent the silencing of primary endings when a muscle is released from stretch. Thus the central nervous system can independently adjust the dynamic and static sensitivity of the different sensory endings in muscle spindles.

instance of reciprocal innervation. This inhibition prevents muscle contractions that might otherwise resist the movements produced by the stretch reflexes.

Sherrington developed an experimental model for investigating spinal circuitry that is especially valuable in

the study of stretch reflexes. He conducted his experiments on cats whose brain stems had been surgically transected at the level of the midbrain, between the superior and inferior colliculi. This is referred to as a *decerebrate preparation*. The effect of this procedure is to

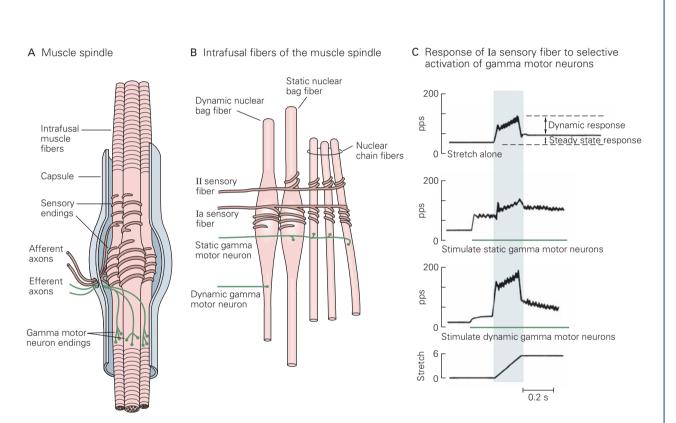

Figure 35–3 The muscle spindle detects changes in muscle length.

A. The main components of the muscle spindle are intrafusal muscle fibers, afferent sensory endings, and efferent motor endings. The intrafusal fibers are specialized muscle fibers with central regions that are not contractile. Gamma motor neurons innervate the contractile polar regions of the intrafusal fibers. Contraction of the polar regions pulls on the central regions of the intrafusal fiber from both ends. The sensory endings spiral around the central regions of the intrafusal fibers and are responsive to stretch of these fibers. (Adapted, with permission, from Hulliger 1984.)

B. The muscle spindle contains three types of intrafusal fibers: dynamic nuclear bag, static nuclear bag, and nuclear chain fibers. A single la sensory axon innervates all three types of fibers, forming a primary sensory ending. Type II sensory axons innervate the nuclear chain fibers

and static bag fibers, forming a secondary sensory ending. Two types of motor neurons innervate different intrafusal fibers. Dynamic gamma motor neurons innervate only dynamic bag fibers; static gamma motor neurons innervate various combinations of chain and static bag fibers. (Adapted, with permission, from Boyd 1980.)

C. Selective stimulation of the two types of gamma motor neurons has different effects on the firing of the la fibers from the spindle. Without gamma stimulation the la fiber shows a small dynamic response to muscle stretch and a modest increase in steady-state firing. When a static gamma motor neuron is stimulated, the steady-state response of the la fiber increases, but there is a decrease in the dynamic response. When a dynamic gamma motor neuron is stimulated, the dynamic response of the la fiber is markedly enhanced, but the steady-state response gradually returns to its original level. (Adapted, with permission, from Brown and Matthews 1966.)

Box 35–2 Classification of Sensory Fibers from Muscle

Sensory fibers are classified according to their diameter. Axons with larger diameters conduct action potentials more rapidly than do fibers of smaller diameters. Because each class of sensory receptors is innervated by fibers with diameters within a restricted range, this method of classification distinguishes to some extent the fibers that arise from the different types of receptor organs. The main groups of sensory fibers from muscle are listed in Table 35–1.

The organization of reflex pathways in the spinal cord has been established primarily by electrically stimulating the sensory fibers and recording evoked responses in different classes of neurons in the spinal cord. This method of activation has three advantages over natural stimulation. The timing of afferent input can be precisely established; the responses evoked in

motor neurons and other neurons by different classes of sensory fibers can be assessed by grading the strength of the electrical stimulus; and certain classes of receptors can be selectively activated.

The strength of the electrical stimulus required to activate a sensory fiber is measured relative to the strength required to activate the afferent fibers with the largest diameter because these fibers have the lowest threshold for electrical activation. The threshold of type I fibers is usually one to two times that of the largest afferents (with Ia fibers having, on average, a slightly lower threshold than Ib fibers). For most type II fibers the threshold is 2 to 5 times higher, whereas type III and IV have thresholds in the range of 10 to 50 times that of the largest afferents.

Table 35-1 Classification of Sensory Fibers from Muscle

Type	Axon	Receptor	Sensitive to
Ia	12–20 μm myelinated	Primary spindle ending	Muscle length and rate of change of length
Ib	12–20 μm myelinated	Golgi tendon organ	Muscle tension
II	6–12 μm myelinated	Secondary spindle ending	Muscle length (little rate sensitivity)
II	6–12 μm myelinated	Nonspindle endings	Deep pressure
Ш	2–6 μm myelinated	Free nerve endings	Pain, chemical stimuli, and temperature (important for physiological responses to exercise)
IV	0.5–2 μm nonmyelinated	Free nerve endings	Pain, chemical stimuli, and temperature

disconnect the rest of the brain from the spinal cord, thus blocking sensations of pain as well as interrupting normal modulation of reflexes by higher brain centers. A decerebrate animal has stereotyped and usually heightened stretch reflexes, making it is easier to examine the factors controlling their expression.

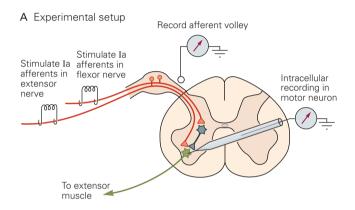

Without control by higher brain centers, descending pathways from the brain stem powerfully facilitate the neuronal circuits involved in the stretch reflexes of extensor muscles. This results in a dramatic increase in extensor muscle tone that sometimes suffices to support the animal in a standing position. In normal animals, owing to the balance between facilitation and inhibition,

stretch reflexes are weaker and considerably more variable in strength than those in decerebrate animals.

Local Spinal Circuits Contribute to the Coordination of Reflex Responses

The Stretch Reflex Involves a Monosynaptic Pathway

The neural circuit responsible for the stretch reflex was one of the first reflex pathways to be examined in detail. The physiological basis of this reflex was examined by measuring the latency of the response in ventral roots to electrical stimulation of dorsal roots. When the Ia sensory axons innervating the muscle spindles were selectively activated, the reflex latency through the spinal cord was less than 1 ms. This demonstrated that the Ia fibers make direct connections on the alpha motor neurons, for the delay at a single synapse is typically 0.5 ms to 0.9 ms (Figure 35–4B).

B Inferring the number of synapses in a pathway

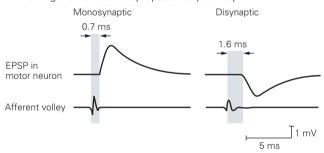

Figure 35–4 The number of synapses in a reflex pathway can be inferred from intracellular recordings.

A. An intracellular recording electrode is inserted into the cell body of a spinal motor neuron that innervates an extensor muscle. Stimulation of la sensory fibers from flexor or extensor muscles produces a volley of action potentials at the dorsal root.

B. Left: When la fibers from an extensor muscle are stimulated, the latency between the recording of the afferent volley and the excitatory postsynaptic potential in the motor neuron is only 0.7 ms. Because this is approximately equal to the duration of signal transmission across a single synapse, it can be inferred that the excitatory action of the stretch reflex pathway is monosynaptic. Right: When la fibers from an antagonist flexor muscle are stimulated, the latency between the recording of the afferent volley and the inhibitory postsynaptic potential in the motor neuron is 1.6 ms. Because this is approximately twice the duration of signal transmission across a single synapse, it can be inferred that the inhibitory action of the stretch reflex pathway is disynaptic.

The pattern of connections of Ia fibers to motor neurons can be shown directly by intracellular recording. Ia fibers from a muscle excite not only the motor neurons innervating the same (homonymous) muscle, but also those innervating other (heteronymous) muscles with a similar mechanical action. The Ia fibers also form inhibitory connections with the alpha motor neurons innervating antagonistic muscles through the Ia inhibitory interneurons. This disynaptic inhibitory pathway is the basis for reciprocal innervation: When a muscle is stretched, its antagonists relax.

Ia Inhibitory Interneurons Coordinate the Muscles Surrounding a Joint

Reciprocal innervation is useful not only in stretch reflexes but also in voluntary movements. Relaxation of the antagonist muscle during a movement enhances speed and efficiency because the muscles that act as prime movers are not working against the contraction of opposing muscles.

The Ia inhibitory interneurons involved in the stretch reflex are also used to coordinate muscle contraction during voluntary movements. These interneurons receive inputs from collaterals of axons descending from neurons in the motor cortex that make direct excitatory connections with spinal motor neurons. This organizational feature simplifies the control of voluntary movements, for higher centers do not have to send separate commands to the opposing muscles.

Sometimes it is advantageous to contract the prime mover and the antagonist at the same time. Such *co-contraction* has the effect of stiffening the joint and is most useful when precision and joint stabilization are critical. An example of this phenomenon is the co-contraction of flexor and extensor muscles of the elbow immediately before catching a ball. The Ia inhibitory interneurons receive both excitatory and inhibitory signals from all of the major descending pathways (Figure 35–5A). By changing the balance of excitatory and inhibitory inputs onto these interneurons, supraspinal centers can reduce reciprocal inhibition of muscles and enable co-contraction, thus controlling the relative amount of joint stiffness to meet the requirements of the motor act.

The activity of spinal motor neurons is also regulated by another important class of inhibitory interneurons, the *Renshaw cells*. Excited by collaterals of the axons of motor neurons, Renshaw cells make inhibitory synaptic connections with several populations of motor neurons, including the motor neurons that excite them and the Ia inhibitory interneurons (Figure 35–5B). The connections with motor neurons form a negative

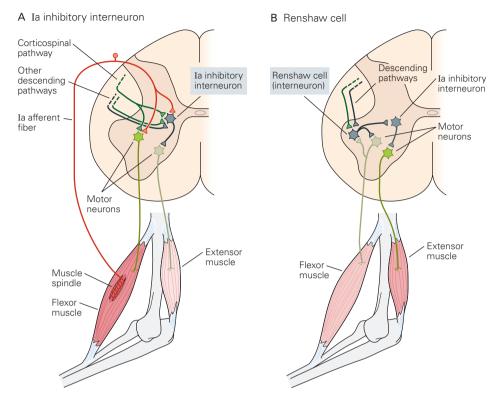

Figure 35–5 Inhibitory spinal interneurons coordinate reflex actions.

A. The la inhibitory interneuron regulates contraction in antagonist muscles in stretch-reflex circuits through its divergent contacts with motor neurons. In addition, the interneuron receives excitatory and inhibitory inputs from corticospinal and other descending pathways. A change in the balance of these supraspinal signals allows the interneuron to coordinate co-contractions in antagonist muscles at a joint.

B. Renshaw cells are spinal interneurons that produce recurrent inhibition of motor neurons. These interneurons are excited by collaterals from motor neurons and inhibit those same motor neurons. This negative feedback system regulates motor neuron excitability and stabilizes firing rates. Renshaw cells also send collaterals to synergist motor neurons (not shown) and la inhibitory interneurons that synapse on antagonist motor neurons. Thus, descending inputs that modulate the excitability of the Renshaw cells adjust the excitability of all the motor neurons around a joint.

feedback system that may help stabilize the firing rate of the motor neurons, whereas the connections with the Ia inhibitory interneurons may regulate the strength of inhibition of antagonistic motor neurons. In addition, Renshaw cells also receive significant synaptic input from descending pathways and distribute inhibition to task-related groups of motor neurons and Ia interneurons. It is therefore likely that Renshaw cells help establish the pattern of signaling in divergent Ia sensory pathways according to the motor task.

Divergence in Reflex Pathways Amplifies Sensory Inputs and Coordinates Muscle Contractions

In all reflex pathways in the spinal cord the sensory neurons form divergent connections with a large number of target neurons through extensive axonal branching. The flexion-withdrawal reflex, for example, involves extensive divergence within the spinal cord. Stimulation of a small number of sensory axons from a small area of skin is sufficient to cause contractions of widely distributed muscles and thus to produce a coordinated motor pattern.

Lorne Mendell and Elwood Henneman used a computer enhancement technique called *spike-triggered averaging* to determine the extent to which the action potentials in single Ia fibers are transmitted to a population of spinal motor neurons. They found that individual Ia axons make excitatory synapses with all homonymous motor neurons innervating the medial gastrocnemius of the cat. This widespread divergence effectively amplifies the signals of individual Ia fibers, leading to a strong excitatory drive to the muscle from which they originate (*autogenic excitation*).

The Ia axons in reflex pathways also provide excitatory inputs to many of the motor neurons innervating synergist muscles (up to 60% of the motor neurons of some synergists). Although widespread, these connections are not as strong as the connections to homonymous motor neurons. The strength of these connections varies from muscle to muscle in a complex way according to the similarity of the mechanical actions of the synergists. We have already noted that, in the control of voluntary movements, descending pathways make use of reciprocal inhibition of antagonists in the stretch reflex. A similar convergence principle holds for the activation of motor neurons innervating synergist muscles. Thus stretch reflex pathways provide a principal mechanism by which the contractions of different muscles can be linked in voluntary as well as reflex actions.

Convergence of Inputs on Ib Interneurons Increases the Flexibility of Reflex Responses

Thus far we have considered reflex pathways as though each included only one type of sensory fiber. But an enormous diversity of sensory information converges on interneurons in the spinal cord.

The *Ib inhibitory interneuron* is one of the best-studied interneurons that receive extensive convergent input. Its principal input is from Golgi tendon organs, sensory receptors that signal the tension in a muscle (Box 35–3), and it makes inhibitory connections with homonymous motor neurons. As one might expect from this connectivity, stimulation of tendon organs or their Ib afferent fibers in passive animals produces disynaptic inhibition of homonymous motor neurons (*autogenic inhibition*). However, stimulation of Ib afferents in active animals does not always inhibit homonymous motor neurons. Indeed, we shall see in the next section that stimulation of tendon organs may in certain conditions excite homonymous motor neurons.

One reason that the reflex actions of the sensory axons from tendon organs are complex in natural situations is that the Ib inhibitory interneurons also receive input from the muscle spindles, cutaneous receptors, and joints (Figure 35–7A). In addition, they receive both excitatory and inhibitory input from various descending pathways.

Golgi tendon organs were first thought to have a protective function, preventing damage to muscle, for it was assumed that they always inhibited homonymous motor neurons and that they fired only when tension in the muscle was high. But we now know that these receptors signal minute changes in muscle tension, thus

providing the nervous system with precise information about the state of a muscle's contraction.

The convergence of sensory input from tendon organs, cutaneous receptors, and joint receptors onto interneurons that inhibit motor neurons may allow for precise spinal control of muscle force in activities such as grasping a delicate object. Additional input from cutaneous receptors may facilitate activity in the Ib inhibitory interneurons when the hand reaches an object, thus reducing the level of muscle contraction and permitting a soft grasp.

Finally, like the Ia fibers from muscle spindles, the Ib fibers from tendon organs form widespread connections with motor neurons that innervate muscles acting at different joints. Therefore the connections of the afferent fibers from tendon organs with the Ib inhibitory interneurons are part of spinal reflex networks that regulate movements of whole limbs.

Central Motor Commands and Cognitive Processes Can Alter Synaptic Transmission in Spinal Reflex Pathways

Both the strength and the sign of synaptic transmission in spinal reflex pathways can be altered during behavioral acts. For example, in humans the strength of the monosynaptic reflex declines as we progress from standing to walking to running. It does so because stiffness increases naturally as muscle force increases, and thus reflexes are not needed.

Another example of a change in sign occurs in the activity of Ib sensory axons during walking. As we have seen, in passive animals the Ib fibers from extensor muscles have an inhibitory effect on homonymous motor neurons. During locomotion they produce an excitatory effect on those same motor neurons because transmission in the disynaptic inhibitory pathway is depressed (Figure 35–7B). This phenomenon is called *state-dependent reflex reversal*.

Transmission in spinal reflex pathways can also be modified in association with higher cognitive functions. Examples are increases in the tendon jerk reflex in the soleus muscle of humans while imagining pressing a foot pedal, and modulation of the Hoffmann reflex in arm and leg muscles when subjects observe grasping and walking movements, respectively. The latter findings indicate that the mirror-neuron system identified in cortical networks (see Chapter 38) influences neuronal systems in the spinal cord. Furthermore, intracellular recordings from monkeys engaged in normal behavior have demonstrated that the intention

Box 35-3 Golgi Tendon Organs

Golgi tendon organs are slender encapsulated structures approximately 1 mm long and 0.1 mm in diameter located at the junction between skeletal muscle fibers and tendon. Each capsule encloses several braided collagen fibers connected in series to a group of muscle fibers.

Each tendon organ is innervated by a single Ib axon that branches into many fine endings inside the capsule; these endings become intertwined with the collagen fascicles (Figure 35–6A).

Stretching of the tendon organ straightens the collagen fibers, thus compressing the Ib nerve endings and causing them to fire. Because the nerve endings are so closely associated with the collagen fibers, even very small stretches of the tendons can compress the nerve endings.

Whereas muscle spindles are most sensitive to changes in length of a muscle, tendon organs are most

sensitive to changes in muscle tension. Contraction of the muscle fibers connected to the collagen fiber bundle containing the receptor is a particularly potent stimulus to a tendon organ. The tendon organs are thus readily activated during normal movements. This has been demonstrated by recordings from single Ib axons in humans making voluntary finger movements and in cats walking normally.

Studies in anesthetized animal preparations have shown that the average level of activity in the population of tendon organs in a muscle is a good index of the total force in a contracting muscle (Figure 35–6B). This close agreement between firing frequency and force is consistent with the view that the tendon organs continuously measure the force in a contracting muscle.

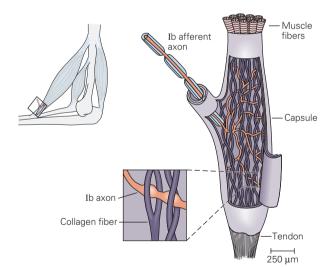

Figure 35–6A When the Golgi tendon organ is stretched (usually because of contraction of the muscle), the Ib afferent axon is compressed by collagen fibers (see inset) and its rate of firing increases. (Adapted, with permission, from Schmidt 1983; inset adapted, with permission, from Swett and Schoultz 1975.)

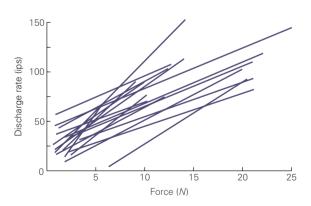

Figure 35–6B The discharge rate of a population of Golgi tendon organs signals the force in a muscle. Linear regression lines show the relationship between discharge rate and force for Golgi tendon organs of the soleus muscle of the cat. (Adapted, with permission, from Crago et al. 1982.)

A. The lb inhibitory interneuron receives input from tendon organs, muscle spindles (not shown), joint and cutaneous receptors, and descending pathways.

B. The action of Ib sensory fibers on extensor motor neurons is reversed from inhibition to excitation when walking is initiated. When the animal is resting, stimulation of Ib fibers from the

ankle extensor muscle inhibits ankle extensor motor neurons through lb inhibitory interneurons, as shown by the hyperpolarization in the record. During walking the lb inhibitory interneurons are inhibited while excitatory interneurons that receive input from lb sensory fibers are facilitated by the command system for walking, thus opening a lb excitatory pathway from the Golgi tendon organs to motor neurons.

to make a movement modifies activity in interneurons in the spinal cord and alters the transmission in spinal reflex pathways.

Central Neurons Can Regulate the Strength of Spinal Reflexes at Three Sites in the Reflex Pathway

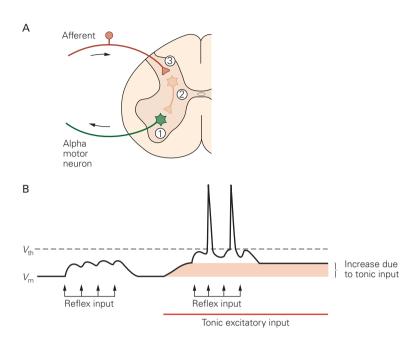

As noted earlier, the force of a reflex can vary, although the sensory stimulus remains constant. This variability in reflex strength is possible because synaptic transmission in spinal reflex pathways can be modified at three possible sites: alpha motor neurons, interneurons in all reflex circuits except monosynaptic pathways with Ia afferent fibers, and the presynaptic terminals of the afferent fibers (Figure 35–8A).

All three sites receive inputs from neurons in motor centers in the brain stem and cerebral cortex as well as other regions of the spinal cord. Signals from these higher-level neurons regulate the strength of reflexes by changing the background (tonic) level of activity at any of the three sites in the spinal reflex pathway. For example, an increase in tonic excitatory input to the alpha motor neurons moves the membrane potential of these cells closer to threshold so that

Figure 35–8 The strength of a spinal reflex can be modulated by changes in synaptic transmission in the reflex pathway.

A. A reflex pathway can be modified at three sites: alpha motor neurons (1), interneurons in polysynaptic pathways (2), and afferent axon terminals (3). Transmitter release from the primary afferent fibers is regulated by presynaptic inhibition (see Figure 12–16).

B. An increase in tonic (background) excitatory input to a motor neuron depolarizes the neuron to a level that enables an otherwise ineffective reflex input (left) to initiate action potentials. The reflex input is represented by a series of excitatory postsynaptic potentials. ($V_{\rm th}$, threshold voltage; $V_{\rm m}$, membrane potential.)

even the slightest reflex input will more easily activate the motor neurons (Figure 35–8B). Another mechanism for modulating the strength of reflexes is to change the physiological properties of motor neurons and perhaps interneurons. Activity in descending monoaminergic systems can alter the properties of motor neurons so they either discharge at a much higher rate in response to the same synaptic input or remain active following a brief excitatory input (see Chapter 34).

Reflex strength can be changed quickly to adapt to the requirements of specific tasks. Intracellular recordings suggest that presynaptic inhibition of the Ia fibers from muscle spindles is particularly important for producing these changes. For example, during locomotion the level of presynaptic inhibition is rhythmically modulated; this action presumably modulates the strength of reflexes during the different phases of the gait cycle (see Chapter 36).

Gamma Motor Neurons Adjust the Sensitivity of Muscle Spindles

Activity of muscle spindles may be modulated by changing the level of activity in the gamma motor neurons, which innervate the intrafusal muscle fibers of muscle spindles (see Box 35–1). This function of gamma motor neurons, often referred to as the fusimotor system, can be demonstrated by selectively stimulating the alpha and gamma motor neurons under experimental conditions.

When only alpha motor neurons are stimulated, the firing of the Ia fiber from the muscle spindle pauses during contraction of the muscle because the muscle is shortening and therefore unloading (slackening) the spindle. However, if gamma motor neurons are activated at the same time as alpha motor neurons, the pause is eliminated. The contraction of the intrafusal fibers by the gamma motor neurons keeps the spindle under tension, thus maintaining the firing rate of the Ia fibers within an optimal range for signaling changes in length, whatever the actual length of the muscle (Figure 35–9). This *alpha-gamma co-activation* thus stabilizes the sensitivity of the muscle spindles and is used in many voluntary movements.

In addition to the axons of gamma motor neurons, axon collaterals of alpha motor neurons sometimes innervate the intrafusal fibers. Axons that innervate both intrafusal and extrafusal muscle fibers are referred to as *beta* axons. Beta axon collaterals provide the equivalent of alpha-gamma coactivation. Beta innervation in spindles exists in both cats and humans, although it is unquantified for most muscles.

The beta fusimotor system's forced linkage of extrafusal and intrafusal contraction highlights the importance of the independent fusimotor system (the gamma motor neurons). Indeed, in lower vertebrates, such as amphibians, beta efferents are the only source of intrafusal innervation. Mammals have evolved a mechanism that frees muscle spindles from complete dependence on the behavior of their parent muscles. In principle

this uncoupling allows greater flexibility in controlling spindle sensitivity for different types of motor tasks.

This conclusion is supported by recordings in spindle sensory afferents during a variety of natural movements in cats. The amount and type of activity in gamma motor neurons are set at steady levels, which vary according to the specific task or context. In general, activity levels in both static and dynamic gamma

motor neurons (see Figure 35–3B) are set at progressively higher levels as the speed and difficulty of the movement increase. Unpredictable conditions, such as when the cat is picked up or handled, lead to marked increases in activity in dynamic gamma motor neurons and thus increased spindle responsiveness when muscles are stretched. When an animal is performing a difficult task, such as walking across a narrow beam,

Figure 35–9 Activation of gamma motor neurons during active muscle contraction maintains muscle spindle sensitivity to muscle length. (Adapted, with permission, from Hunt and Kuffler 1951.)

A. Sustained tension elicits steady firing in the la sensory fiber from the muscle spindle (the two muscle fibers are shown separately for illustration only).

B. A characteristic pause occurs in the discharge of the la fiber when the alpha motor neuron is stimulated, causing a brief contraction of the muscle. The la fiber stops firing because the spindle is unloaded by the contraction.

C. Gamma motor neurons innervate the contractile polar regions of the intrafusal fibers of muscle spindles (see Figure 35–3A). If a gamma motor neuron is stimulated at the same time as the alpha motor neuron, the spindle is not unloaded during the contraction. As a result, the pause in discharge of the la sensory fiber that occurs when only the alpha motor neuron is stimulated is "filled in" by the response of the fiber to stimulation of the gamma motor neuron.

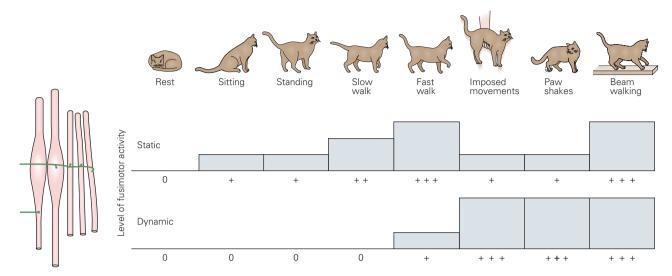

Figure 35–10 The level of activity in the fusimotor system varies with the type of behavior. Only static gamma motor neurons are active during activities in which muscle length changes slowly and predictably. Dynamic gamma motor

neurons are activated during behaviors in which muscle length may change rapidly and unpredictably. (Adapted, with permission, from Prochazka et al. 1988.)

both static and dynamic gamma activation are at high levels (Figure 35–10).

Thus the nervous system uses the fusimotor system to fine-tune muscle spindles so that the ensemble output of the spindles provides information most appropriate for a task. The task conditions under which independent control of alpha and gamma motor neurons occurs in humans have not yet been clearly established.

Proprioceptive Reflexes Play an Important Role in Regulating Both Voluntary and Automatic Movements

All movements activate receptors in muscles, joints, and skin. Sensory signals generated by the body's own movements were termed *proprioceptive* by Sherrington, who proposed that they control important aspects of normal movements. A good example is the Hering-Breuer reflex, which regulates the amplitude of inspiration. Stretch receptors in the lungs are activated during inspiration, and the Hering-Breuer reflex eventually triggers the transition from inspiration to expiration when the lungs are expanded.

A similar situation exists in the walking systems of many animals; sensory signals generated near the end of the stance phase initiate the onset of the swing phase (see Chapter 36). Proprioceptive signals can also

contribute to the regulation of motor activity during voluntary movements, as has been shown in recent studies of individuals with sensory neuropathy of the arms. These patients display abnormal reaching movements and have difficulty in positioning the limb accurately because the lack of proprioception results in a failure to compensate for the complex inertial properties of the human arm.

Therefore, a primary function of proprioceptive reflexes in regulating voluntary movements is to adjust the motor output according to the changing biomechanical state of the body and limbs. This adjustment ensures a coordinated pattern of motor activity during an evolving movement and compensates for the intrinsic variability of motor output.

Reflexes Involving Limb Muscles Are Mediated Through Spinal and Supraspinal Pathways

Reflexes involving the limbs are mediated by multiple pathways acting in parallel through spinal and supraspinal pathways. Consider the response evoked by a sudden stretch of a flexor muscle of the thumb. This response has two discrete components. The first, the M1 response, is generated by the monosynaptic connection of muscle spindle afferents to the spinal motor neurons. The second, the M2 response, is also a reflex because its latency is shorter than the voluntary reaction time (Figure 35–11A).

The M2 response has been observed in virtually all limb muscles. In the distal muscles the M2 responses are mediated by pathways that include the motor cortex, as shown in studies of patients with Klippel-Feil syndrome. In this unusual condition axons descending from neurons in the motor cortex bifurcate and make connections to homologous motor neurons on

both sides of the body. Thus, when the individual voluntarily moves the fingers of one hand, these movements are mirrored by movements of the fingers of the other (Figure 35–11B). Similarly, when the M2 component is evoked by stretching muscles of one hand, a response with the same latency is evoked in the corresponding muscle of the other hand, even though no

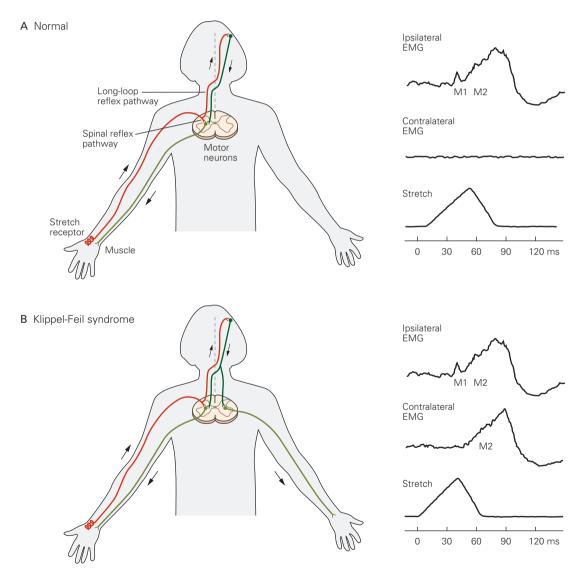

Figure 35–11 Reflexes of the limbs are mediated by spinal reflex pathways and long-loop pathways that involve the motor cortex. (Adapted, with permission, from Matthews 1991.)

A. In normal individuals a brief stretch of a thumb muscle produces a response that has two components. A short-latency response (M1) in the stretched muscle is controlled by the spinal reflex pathway, the monosynaptic connection between

muscle spindle afferents and spinal motor neurons. This is followed by a long-latency response (M2) controlled by a pathway that loops through the motor cortex.

B. In individuals with Klippel-Feil syndrome the M2 response is evoked bilaterally because neurons in the motor cortex activate motor neurons bilaterally.

M1 response has occurred in the other hand. The reflex pathway responsible for the M2 response must therefore traverse the motor cortex (Figure 35–11B).

Reflex responses mediated through the motor cortex and other supraspinal structures, the *long-loop reflexes*, have been investigated in numerous muscles in humans and other animals. The general conclusion is that long-loop reflexes via the cortex are of primary importance in regulating contractions in distal muscles, whereas subcortical reflex pathways are largely responsible for regulating the contractions of proximal muscles.

This type of organization is related to functional demands. Many tasks involving distal muscles require precise regulation by voluntary commands. By transmitting sensory signals to regions of cortex most involved in controlling voluntary movements, motor commands can be quickly adapted to the evolving needs of a task. More automatic motor functions, such as maintaining balance and producing gross bodily movements, can be efficiently executed largely through subcortical and spinal pathways.

Pioneering studies by Edward Evarts in the 1960s revealed that activity in approximately 50% of neurons in the motor cortex is modified in response to loading muscles during the voluntary maintenance of wrist position and during simple movements at the wrist. This early finding was initially interpreted as evidence that long-loop cortical reflexes are involved in compensating for change in loading conditions by functioning as online negative feedback controllers. However, subsequent studies on multijoint movements revealed complex response patterns in cortical neurons, many of which are not consistent with this concept. Moreover, the long delays in transmission in long-loop reflexes make these reflexes inappropriate for a direct role in load compensation because the potential delays would create instabilities.

Currently the function of proprioceptive input to the motor cortex in the volitional control of movement remains a puzzle. One contemporary notion is that proprioceptive input is integrated into internal models for estimating the state of the system (see Chapter 33). Another hypothesis is that proprioceptive inputs play a key role in motor cortical circuits that function as optimal feedback controllers, which use only those sensory signals that are required for attaining a specific goal.

Stretch Reflexes Reinforce Central Commands for Movements

Stretch-reflex pathways can contribute to regulation of motor neurons during voluntary movements and maintenance of posture because they form closed feedback loops. For example, stretching a muscle increases activity in spindle sensory afferents, leading to muscle contraction and consequent shortening of the muscle. Muscle shortening in turn leads to decreased activity in spindle afferents, reduction of muscle contraction, and lengthening of the muscle.

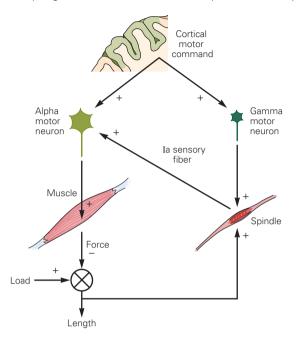

The stretch reflex loop thus acts continuously—the output of the system, a change in muscle length, becomes the input—tending to keep the muscle close to a desired or reference length. The stretch reflex is a negative feedback system, or *servomechanism*, because it tends to counteract or reduce deviations from the reference value of the regulated variable.

In 1963 Ragnar Granit proposed that the reference value in voluntary movements is set by descending signals that act on both alpha and gamma motor neurons. The rate of firing of alpha motor neurons is set to produce the desired shortening of the muscle, and the rate of firing of gamma motor neurons is set to produce an equivalent shortening of the intrafusal fibers of the muscle spindle. If the shortening of the whole muscle is less than that required by a task, as when the load is greater than anticipated, the sensory fibers increase their firing rate because the contracting intrafusal fibers are stretched (loaded) by the relatively greater length of the whole muscle. If shortening is greater than necessary, the sensory fibers decrease their firing rate because the intrafusal fibers are relatively slackened (unloaded) (Figure 35–12A).

In theory this mechanism could permit the nervous system to produce a movement of a given distance without having to know in advance the actual load or weight being moved. In practice, however, the stretchreflex pathways do not have sufficient control over motor neurons to overcome large unexpected loads. This is immediately obvious if we consider what happens when we attempt to lift a heavy suitcase that we believe to be empty. Automatic compensation for the greater-than-anticipated load does not occur. Instead, we have to pause briefly to plan a new movement with much greater muscle activation. Thus, rather than providing compensation for large unexpected loads, monosynaptic and long-loop stretch reflex pathways may compensate for small changes in load and intrinsic irregularities in the muscle contraction, with the relative contribution of each pathway dependent on the muscle and the task.

Strong evidence that alpha and gamma motor neurons are co-activated during voluntary human movement has come from direct measurements of the activity of muscle spindles. In the late 1960s Åke Vallbo and Karl-Erik Hagbarth developed microneurography, a technique for recording from the largest afferent fibers

A Alpha-gamma co-activation reinforces alpha motor activity

B Spindle activity increases during muscle shortening

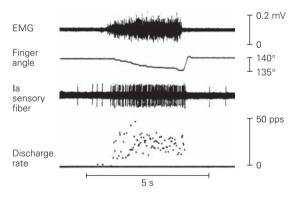

Figure 35–12 Alpha and gamma motor neurons are coactivated during voluntary movements.

A. Co-activation of alpha and gamma motor neurons by a cortical motor command allows feedback from muscle spindles to reinforce activation in the alpha motor neurons. Because any disturbance during a movement alters the length of the muscle and changes the activity in the muscle spindles, altering the spindle input to the alpha motor neuron compensates for the disturbance.

B. The discharge rate in the la sensory fiber of a spindle increases during slow flexion of a finger. This increase depends on alpha-gamma co-activation. If the gamma motor neurons were not active, the spindle would slacken, and its discharge rate would decrease as the muscle shortened (see Figure 35–9C). (Adapted, with permission, from Vallbo 1981.)

in peripheral nerves. Vallbo later showed that during slow movements of the fingers the large-diameter Ia fibers from spindles in the contracting muscles increase their rate of firing even when the muscle shortens as it contracts (Figure 35–12B). This occurs because the gamma motor neurons, which have direct excitatory connections with spindles, are co-activated with alpha motor neurons.

Furthermore, when subjects attempt to make slow movements at a constant velocity, the firing of the Ia fibers mirrors small deviations in velocity in the trajectory of the movements (sometimes the muscle shortens quickly and other times more slowly). When the velocity of flexion increases transiently, the rate of firing in the fibers decreases because the muscle is shortening more rapidly and therefore exerts less tension on the intrafusal fibers. When the velocity decreases, firing increases because the muscle is shortening more slowly, and therefore the relative tension on the intrafusal fibers increases. This information can be used by the nervous system to compensate for irregularities in the movement trajectory by exciting the alpha motor neurons.

Damage to the Central Nervous System Produces Characteristic Alterations in Reflex Response and Muscle Tone

Stretch reflexes can be evoked in many muscles throughout the body and are routinely used in clinical examinations of patients with neurological disorders. They are typically elicited by sharply tapping the tendon of a muscle with a reflex hammer.

Although the responses are often called tendon reflexes or tendon jerks, the receptor that is stimulated, the muscle spindle, actually lies in the muscle rather than the tendon. Only the primary sensory fibers in the spindle participate in the tendon reflex, for these are selectively activated by a rapid stretch of the muscle produced by the tendon tap. An electrical analog of the tendon jerk is the Hoffmann reflex (Box 35–4).

Measuring alterations in the strength of the stretch reflex can assist in the diagnosis of certain conditions and in localizing injury or disease in the central nervous system. Absent or hypoactive stretch reflexes often indicate a disorder of one or more of the components of the peripheral reflex pathway: sensory or motor axons, the cell bodies of motor neurons, or the muscle itself. Nevertheless, because the excitability of motor neurons is dependent on descending excitatory and inhibitory signals, absent or hypoactive stretch reflexes can also result from lesions of the central nervous system.

Box 35–4 The Hoffmann Reflex

The characteristics of the monosynaptic connections from Ia sensory fibers to spinal motor neurons in humans can be studied using an important technique introduced in the 1950s and based on early work by Paul Hoffmann. This technique involves electrically stimulating the Ia fibers in a peripheral nerve and recording the reflex response in the homonymous muscle. The response is known as the *Hoffmann reflex*, or H-reflex (Figure 35–13A).

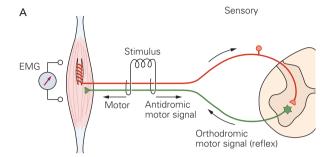

The H-reflex is readily measured in the soleus muscle, an ankle extensor. The Ia fibers from the soleus and its synergists are excited by an electrode placed above the tibial nerve behind the knee. The response recorded from the soleus muscle depends on stimulus strength. At low stimulus strengths a pure H-reflex is evoked, for the threshold for activation of the Ia fibers is lower than the threshold for motor axons. Increasing the stimulus strength excites the motor axons innervating the soleus, producing two successive responses.

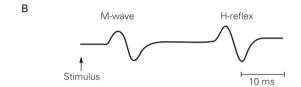

The first results from direct activation of the motor axons, and the second is the H-reflex evoked by stimulation of the Ia fibers (Figure 35–13B). These two components of the evoked electromyogram are called the M-wave and H-wave. The H-wave occurs later because it results from signals that travel to the spinal cord, across a synapse, and back again to the muscle. The M-wave, in contrast, results from direct stimulation of the motor axon innervating the muscle.

As the stimulus strength is increased still further, the M-wave continues to become larger and the H-wave progressively declines (Figure 35–13C). The decline in the H-wave amplitude occurs because action potentials in the motor axons propagate toward the cell body (antidromic conduction) and cancel reflexively evoked action potentials in the same motor axons. At very high stimulus strengths only the M-wave persists.

An interesting feature of the H-reflex is that its magnitude depends on motor experience. For example, it is low in highly trained ballet dancers and varies among different kinds of athletes. This strongly suggests that modification of spinal reflexes is an important process in learning motor skills.

Extensive studies of humans, monkeys, and rats by Jonathan Wolpaw and his colleagues have demonstrated that H-reflexes can be operantly conditioned to either increase or decrease. The mechanisms underlying these changes are complex and involve alterations at multiple sites including changes in motor neuron properties. For down-conditioning they are dependent on corticospinal signals.

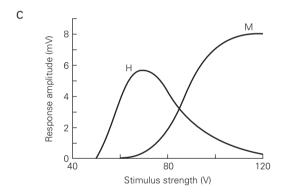

Figure 35-13 The Hoffmann reflex.

A. The Hoffmann reflex (H-reflex) is evoked by electrically stimulating la sensory fibers from muscle spindles in mixed nerves. The sensory fibers excite alpha motor neurons, which in turn activate the muscle. Muscle activation is detected by the electromyogram (EMG).

B. At intermediate stimulus strengths motor axons in the mixed nerve are excited in addition to the spindle afferents. Excitation of the motor neurons produces an M-wave that precedes the H-wave (H-reflex) in the EMG.

C. At low stimulus strengths only an H-wave is produced because only the spindle afferents are excited. As the stimulus strength increases, the magnitude of the H-reflex also increases, then declines, because the orthodromic motor signals generated reflexively by the spindle afferents are cancelled by antidromic signals initiated by the electrical stimulus in the same motor axons. At very high stimulus strengths only an M-wave is evoked. (Adapted, with permission, from Schieppati 1987.)

Hyperactive stretch reflexes, conversely, always indicate that the lesion is in the central nervous system.

Interruption of Descending Pathways to the Spinal Cord Frequently Produces Spasticity

Muscle tone, the force with which a muscle resists being lengthened, depends on the muscle's intrinsic elasticity, or stiffness. Because a muscle has elastic elements in series and parallel that resist lengthening, it behaves like a spring. However, there is also a neural contribution to muscle tone; the feedback loop inherent in the stretch reflex pathway acts to resist lengthening of the muscle. The local neural circuits responsible for stretch reflexes provide the brain with a mechanism for adjusting muscle tone to suit different circumstances.

Because the strength of stretch reflexes is controlled by higher brain centers, disorders of muscle tone are frequently associated with lesions of the motor system, especially those that interfere with descending motor pathways. These conditions may involve either an abnormal increase in tone (*hypertonus*) or a decrease (*hypotonus*). The most common form of hypertonus is spasticity, which is characterized by hyperactive tendon jerks and an increase in resistance to rapid stretching of the muscle. A slowly applied stretch in a patient with spasticity elicits little resistance; as the speed of the stretch is increased, resistance to the stretch also rises progressively.

Thus spasticity is primarily a phasic phenomenon. An active reflex contraction occurs only during a rapid stretch; when the muscle is held in a lengthened position the reflex contraction subsides. In some patients, however, the hypertonus also has a tonic component; that is, the reflex contraction continues even after the muscle is no longer being lengthened.

The pathophysiology of spasticity is still unclear. It was long thought that hyperactivity of stretch reflexes in spasticity resulted from overactivity of the gamma motor neurons. Recent experiments have cast doubt on this explanation. Although gamma motor neurons may be overactive in some cases, changes in the background activity of alpha motor neurons and interneurons are probably more important. Especially important may be modifications in the properties of motor neurons that enable sustained firing in response to brief excitatory input (see Chapter 34).

Whatever the precise mechanism that produces spasticity, the effect is a strong facilitation of synaptic transmission in the Ia sensory fibers in the monosynaptic reflex pathway. Indeed, this can provide a mechanism for treatment. A common therapeutic procedure today is to mimic presynaptic inhibition in the terminals

of the Ia fibers by intrathecally administering the drug baclofen to the spinal cord. Baclofen is an agonist of GABA_B (γ-aminobutyric acid) receptors; binding of the drug to these receptors decreases the influx of Ca²⁺ into presynaptic terminals, reducing transmitter release.

Transection of the Spinal Cord in Humans Leads to a Period of Spinal Shock Followed by Hyperreflexia

Damage to the spinal cord can cause large changes in the strength of spinal reflexes. Each year approximately 11,000 Americans sustain spinal cord injuries. More than half of these injuries produce permanent disability, including impairment of motor and sensory functions and loss of voluntary bowel and bladder control. Approximately 250,000 people in the United States today have some permanent disability from spinal cord injury.

When the spinal cord is completely transected, there is usually a period immediately after the injury when all spinal reflexes below the level of the transection are reduced or completely suppressed. This condition is known as *spinal shock*. During the course of weeks and months spinal reflexes gradually return, often greatly exaggerated. For example, a light touch to the skin of the foot may elicit strong flexion withdrawal of the leg.

The mechanisms underlying spinal shock and recovery are poorly understood. The initial shock is thought to result from the sudden withdrawal of tonic facilitatory influence from the brain. Several mechanisms may contribute to the recovery, including sprouting of afferent sensory terminals and denervation supersensitivity owing to increased numbers of postsynaptic receptors.

Interestingly, the period of recovery from spinal shock is much shorter in animals than in humans. In nonhuman primates the recovery period is rarely more than a week; in cats and dogs it is only a few hours. The longer recovery period for humans presumably reflects the greater influence of supraspinal centers on spinal reflex circuits. This may in turn reflect the increased complexity of upright bipedal locomotion. Indeed, as we shall see in the next chapter, in humans with spinal cord injury the recovery of automatic locomotor patterns is slight compared with that of quadrupedal mammals.

An Overall View

Reflexes are coordinated, involuntary motor responses initiated by a stimulus applied to peripheral receptors. Some reflexes initiate movements to avoid potentially hazardous situations, whereas others automatically adapt motor patterns to achieve or maintain a behavioral goal. The actual response evoked by a reflex depends on mechanisms that set the strength and pattern of responses according to the task and the behavioral state, or functional set. We know little about the details of these mechanisms, except that modification of synaptic transmission in spinal reflex pathways by descending signals from the brain is thought to be an important factor.

Many groups of interneurons in spinal reflex pathways are also involved in producing complex movements such as walking and transmitting voluntary commands from the brain. In addition, some components of reflex responses, particularly those involving the limbs, are mediated by supraspinal centers, such as brain stem nuclei, the cerebellum, and the motor cortex. Reflexes can be smoothly integrated into centrally generated motor commands because of the convergence of sensory signals onto spinal and supraspinal interneuronal systems involved in initiating movements. Establishing the details of these integrative events is one of the major challenges of contemporary research on reflex regulation of movement.

Because of the role of supraspinal centers in spinal reflex pathways, injury to or disease of the central nervous system often results in significant alterations in the strength of spinal reflexes. The pattern of changes provides an important aid to diagnosis of patients with neurological disorders.

of animals. Although many forms of locomotion have evolved—swimming, flying, crawling, and walking—all use rhythmic and alternating movements of the body or appendages. This rhythmicity makes locomotion appear to be repetitive and stereotyped. Indeed, locomotion is controlled automatically at relatively low levels of the central nervous system without intervention by higher centers. Nevertheless, locomotion often takes place in environments that are either unfamiliar or present unpredictable conditions. Locomotor movements must therefore be continually modified, usually in a subtle fashion, to adapt otherwise stereotyped movement patterns to the immediate surroundings.

The study of the neural control of locomotion must address two fundamental questions. First, how do assemblies of nerve cells generate the rhythmic motor patterns associated with locomotor movements? Second, how does sensory information adjust locomotion to both anticipated and unexpected events in the environment? In this chapter we address both of these questions by examining the neural mechanisms controlling walking.

Although most information on neural control of walking has come from studying the cat's stepping movements, important insights have also come from studies of other animals as well as rhythmic behaviors other than locomotion. Therefore, we shall also consider the more general question of how rhythmic motor activity can be generated and sustained by networks of neurons.

Several critical insights into the neural mechanisms controlling quadrupedal stepping were obtained

nearly a century ago when it was found that removing the cerebral hemispheres in dogs did not abolish walking—decerebrate animals are still able to walk spontaneously. One animal was observed to rear itself up in order to rest its forepaws on a gate at feeding time. It was soon discovered that stepping of the hind legs could be induced in cats and dogs after complete transection of the spinal cord. The stepping movements in these spinal preparations (Box 36-1) are similar to normal stepping. Nonrhythmic electrical stimulation of the cut cord elicits stepping at a rate related to the intensity of the stimulating current. Another important early observation was that passive movement of a limb by the experimenter could initiate stepping movements in spinal cats and dogs, suggesting that proprioceptive reflexes are crucial in regulating the movements.

Finally, in 1911 Thomas Graham Brown discovered that rhythmic, alternating contractions could be evoked in deafferented hind leg muscles immediately after transection of the spinal cord. He therefore proposed the concept of the half-center, whereby flexors and extensors inhibit each other reciprocally, giving rise to alternating stepping movements. Four conclusions can be drawn from these early studies.

- 1. Supraspinal commands are not necessary for producing the basic motor pattern for stepping.
- 2. The basic rhythmicity of stepping is produced by neuronal circuits contained entirely within the spinal cord.
- 3. The spinal circuits can be modulated by tonic descending signals from the brain.
- 4. The spinal pattern-generating networks do not require sensory input but nevertheless are strongly regulated by input from limb proprioceptors.

For almost half a century following these early studies few investigations were aimed at establishing the neural mechanisms for walking. Instead, research on motor systems focused on the organization of spinal reflex pathways and the mechanisms of synaptic integration within the spinal cord (see Chapter 35). Modern research on the neural control of locomotion dates from the 1960s and two major experimental successes. First, rhythmic patterns of motor activity were elicited in spinal animals by the application of adrenergic drugs. Second, walking on a treadmill was evoked in decerebrate cats by electrical stimulation of a small region in the brain stem.

At about the same time electromyographic recordings from numerous hind leg muscles in intact cats

during unrestrained walking revealed the complexity of the locomotor pattern and brought to prominence the question of how spinal reflexes are integrated with intrinsic spinal circuits to produce the locomotor pattern. Soon thereafter, investigations of stepping in spinal cats demonstrated the similarity of locomotor patterns in spinal preparations and intact animals, thus firmly establishing the idea that the motor output for locomotion is produced primarily by a neuronal system in the spinal cord.

A Complex Sequence of Muscle Contractions Is Required for Stepping

For the purpose of examining the patterns of muscle contraction during locomotion, the step cycle in cats and humans can be divided into four distinct phases: flexion (F), first extension (E_1), second extension (E_2), and third extension (E_3) (Figure 36–2A). The F and E_1 phases occur during the time the foot is off the ground (*swing*), whereas E_2 and E_3 occur when the foot is in contact with the ground (*stance*).

Swing commences with flexion at the hip, knee, and ankle (the F phase). Approximately midway through swing the knee and ankle begin to extend while the hip continues to flex (the E₁ phase). Extension at the knee and ankle during E₁ moves the foot ahead of the body and prepares the leg to accept weight in anticipation of foot contact at the onset of stance. During early stance (the E₂ phase) the knee and ankle joints flex, even though extensor muscles are contracting strongly. A lengthening contraction of ankle and knee extensor muscles occurs because weight is being transferred to the leg. The spring-like yielding of these muscles as weight is accepted allows the body to move smoothly over the foot, and is essential for establishing an efficient gait. During late stance (the E₃ phase) the hip, knee, and ankle all extend to provide a propulsive force to move the body forward.

The rhythmic movements of the legs during stepping are produced by contractions of many muscles. In general, contractions of flexor muscles occur during the F phase, whereas contractions of extensor muscles occur during one or more of the E phases. However, the timing and amounts of activity are different in different muscles (Figure 36–2B). For example, a hip flexor muscle (iliopsoas) contracts continuously during the F and E_1 phases, whereas a knee flexor muscle (semitendinosus) contracts briefly at the beginning of the F and E_2 phases. Another complexity is that some

Box 36–1 Preparations Used to Study the Neural Control of Stepping

The literature on the neural control of quadrupedal stepping can be confusing because different experimental preparations are used in different studies. In addition to intact animals, spinal and decerebrate cats are commonly used in studies of the neural mechanisms of locomotor rhythmicity. Moreover, each of these preparations may be used in two experimental strategies, deafferentation and immobilization, depending on what is being investigated. Finally, neonatal rat and mouse preparations have proven useful for analyzing the cellular properties of neurons generating the locomotor rhythm.

Spinal Preparations

In spinal preparations the spinal cord is transected at the lower thoracic level (Figure 36–1A), thus isolating the spinal segments that control the hind limb musculature from the rest of the central nervous system. This allows investigations of the role of spinal circuits in generating rhythmic locomotor patterns.

In *acute* spinal preparations adrenergic drugs such as L-DOPA (L-dihydroxyphenylalanine) and nialamide are administered immediately after the transection. These drugs elevate the level of norepinephrine in the spinal cord and lead to the spontaneous generation of locomotor activity approximately 30 minutes after administration. Clonidine, another adrenergic drug, enables locomotor activity to be generated in acute spinal preparations but only if the skin of the perineal region is also stimulated.

In *chronic* spinal preparations animals are studied for weeks or months after transection. Without drug treatment locomotor activity can return within a few weeks of cord transection. Locomotor function returns spontaneously in kittens, but in adult cats daily training is usually required.

Decerebrate Preparations

In decerebrate preparations the brain stem is completely transected at the level of the midbrain, disconnecting rostral brain centers, especially the cerebral cortex, from the spinal centers where the locomotor pattern is generated. Because brain stem centers remain connected to the spinal cord, these preparations allow investigation of the role of the cerebellum and brain stem structures in controlling locomotion.

Two decerebrate preparations are commonly used. In one the locomotor rhythm is generated spontaneously, whereas in the other it is evoked by electrical stimulation of the mesencephalic locomotor region. This difference depends on the level of decerebration. Spontaneous walking occurs in *premammillary preparations*, in which the brain stem is transected from the rostral margin of the superior colliculi to a point immediately rostral to the mammillary bodies. When the transection is made caudal to the mammillary bodies *postmammillary*

or mesencephalic preparation, spontaneous stepping does not occur; rather, electrical stimulation of the mesencephalic locomotor region is required to evoke walking (Figure 36–1B).

When supported on a motorized treadmill, both preparations walk with a coordinated stepping pattern in all four limbs and the rate of stepping is matched to the treadmill speed. The motor activity can be recorded during stepping, and sensory nerves can be stimulated with implanted electrodes to examine the reflex mechanisms that regulate stepping.

Deafferented Preparations

An early view of the neural control of locomotion was that it involved a "chaining" of reflexes: Successive stretch reflexes in flexor and extensor muscles were thought to produce the basic rhythm of walking. This view was disproved by Graham Brown, who showed that rhythmic locomotor patterns were generated even after complete removal of all sensory input (deafferentation) from the moving limbs.

Deafferentation is accomplished by transection of all the dorsal roots that innervate the limbs. Because the dorsal roots carry only sensory axons, motor innervation of the muscles remains intact. Deafferented preparations were once useful for demonstrating the capabilities of the isolated spinal cord but are rarely used today, principally because the loss of all tonic sensory input drastically reduces the excitability of interneurons and motor neurons in the spinal cord. Thus, changes in the locomotor pattern after deafferentation might result from the artificial reduction in excitability of neurons rather than from the loss of specific sensory inputs.

Immobilized Preparations

The role of proprioceptive input from the limbs can be more systematically investigated by preventing activity in motor neurons from actually causing any movement. This is typically accomplished by paralyzing the muscles with d-tubocurarine, a competitive inhibitor of acetylcholine that blocks synaptic transmission at the neuromuscular junction.

When locomotion is initiated in such an immobilized preparation, often referred to as fictive locomotion, the motor nerves to flexor and extensor muscles fire alternately but no actual movement takes place and the proprioceptive afferents are not phasically excited. Thus the effect of proprioceptive reflexes is removed whereas tonic sensory input is preserved.

Because immobilized preparations allow intracellular and extracellular recording from neurons in the spinal cord, they are used to examine the synaptic events associated with locomotor activity and the organization of central and reflex pathways controlling locomotion.

Neonatal Rodent Preparation

The spinal cord is removed from a neonatal rat or mouse (0–5 days after birth) and placed in a saline bath, where it will generate coordinated bursts of activity in leg motor neurons when exposed to NMDA and serotonin (Figure 36–1C). This preparation allows more detailed

analysis of the locations and roles of the specific neurons involved in rhythm generation, as well as pharmacological studies on the rhythm-generating network.

The ability to genetically modify neurons in the spinal cord of mice allows studies on the function of identified classes of neurons in these animals.

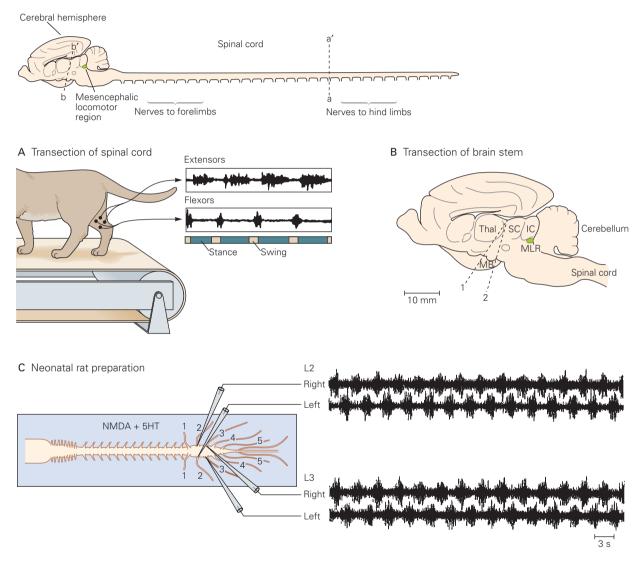

Figure 36–1 A. Transection of the spinal cord of a cat at the level a-a' isolates the segments of the cord with nerves that project to the hind limbs. The hind limbs are still able to step on a treadmill either immediately after recovery from surgery if adrenergic drugs are administered or a few weeks after surgery if the animal is exercised regularly on the treadmill. Transection of the brain stem at the level b-b' isolates the spinal cord and lower brain stem from the cerebral hemispheres.

B. Depending on the exact level of the transection of the brain stem, locomotion occurs spontaneously (1) or can be initiated by electrical stimulation of the mesencephalic locomotor region (MLR) (2). The mesencephalic locomo-

tor region is a small region of the brain stem close to the cuneiform nucleus approximately 6 mm below the surface of the inferior colliculus (IC). (Thal, thalamus; SC, superior colliculus; MB, mammillary body.)

C. The spinal cord is removed from a neonatal rat and placed in a saline bath. Addition of *N*-methyl-p-aspartate (NMDA) and serotonin (5-hydroxytryptamine, or 5-HT) to the bath elicits rhythmic bursting in the motor neurons supplying leg muscles, as shown in recordings from nerve roots of the second (L2) and third (L3) lumbar segments. Intracellular or tight-seal recordings can also be made from lumbar neurons during periods of rhythmic activity. (Adapted, with permission, from Cazalets, Borde, and Clarac 1995.)

A Four phases of the step cycle

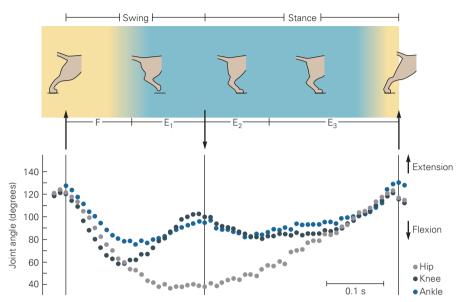

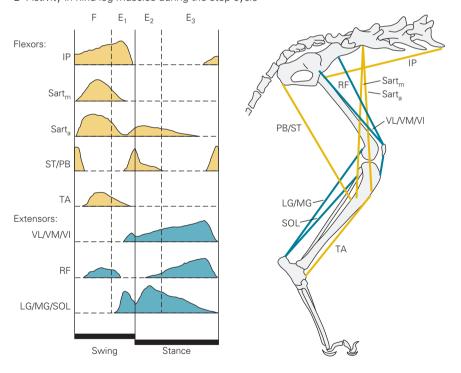

Figure 36–2 Stepping is produced by complex patterns of contractions in leg muscles.

A. The step cycle is divided into four phases: the flexion (F) and first extension (E_1) phases occur during swing, when the foot is off the ground, whereas second extension (E_2) and third extension (E_3) occur during stance, when the foot contacts the ground. Second extension is characterized by flexion at the knee and ankle as the leg begins to bear the animal's weight. The contracting knee and ankle extensor muscles lengthen during this phase. (Adapted, with permission, from Engberg and Lundberg 1969.)

B. Profiles of electrical activity in some of the hind leg flexor and extensor muscles in the cat during stepping. Although flexor and extensor muscles are generally active during swing and stance, respectively, the overall pattern of activity is complex in both timing and amplitude. (IP, iliopsoas; LG and MG, lateral and medial gastrocnemius; PB, posterior biceps; RF, rectus femoris; Sart_m and Sart_a, medial and anterior sartorius; SOL, soleus; ST, semitendinosus; TA, tibialis anterior; VL, VM, and VI, vastus lateralis, medialis, and intermedialis.)

muscles contract during both swing and stance. Thus the motor pattern for stepping is not merely alternating flexion and extension at each joint, but a complex sequence of muscle contractions, each precisely timed and scaled to achieve a specific task in the act of locomotion.

The Motor Pattern for Stepping Is Organized at the Spinal Level

Transection of the spinal cord of quadrupeds initially causes complete paralysis of the hind legs. It does not, however, permanently abolish the capacity of hind

legs to make stepping movements: Hind leg stepping often recovers spontaneously over a period of a few weeks, particularly if the transection is made in young animals. Recovery of stepping in adult cats can be facilitated by daily training on a treadmill evoked by nonspecific cutaneous stimulation of the perineal region.

Electromyographic records of the hind leg muscles of chronic spinal cats during stepping are quite similar to those of normally walking animals. Many of the reflex responses that occur in normal animals can also be evoked in spinal animals. Spinal animals are not, however, able to maintain balance on the treadmill. Adequate control of balance requires descending signals from brain stem centers, such as the vestibular nuclei.

Contraction in Flexor and Extensor Muscles of the Hind Legs Is Controlled by Mutually Inhibiting Networks

From the studies by Graham Brown early in the 20th century we know that the isolated spinal cord can generate rhythmic bursts of reciprocal activity in flexor and extensor motor neurons of the hind legs even in the absence of sensory input (Figure 36–3). Graham Brown proposed that contractions in the flexor and extensor muscles are controlled by two systems of neurons, or *half-centers*, that mutually inhibit each other (Figure 36–4B).

According to Graham Brown, activity alternates between half-centers because of fatigue of the inhibitory connections. For example, if two half-centers receive tonic excitatory input, and the flexor half-center receives the stronger input, the flexor muscles will contract while the extensor half-center is inhibited. Then, as the inhibitory output fatigues, the extensor half-center's output will increase, causing inhibition of the flexor half-center and contraction of the extensor muscles until its inhibitory output fatigues. Thus the flexor and extensor muscles controlled by the two half-centers will alternately contract and relax as long as the half-centers receive sufficient tonic excitatory input.

The half-center hypothesis was supported by studies in the 1960s on the effects in spinal cats of the drug L-dihydroxyphenylalanine (L-DOPA), a precursor of the monoamine transmitters dopamine and norepinephrine. After the cats were treated with L-DOPA, brief

Figure 36–3 Rhythmic activity for stepping is generated by networks of neurons in the spinal cord. The existence of such spinal networks was first demonstrated by Thomas Graham Brown in 1911. Graham Brown developed an experimental preparation system in which dorsal roots were cut so that sensory information from the limbs could not reach the spinal cord. An original record from Graham Brown's study shows that rhythmic alternating contractions of ankle flexor (tibialis anterior) and extensor (gastrocnemius) muscles begin immediately after transection of the spinal cord.

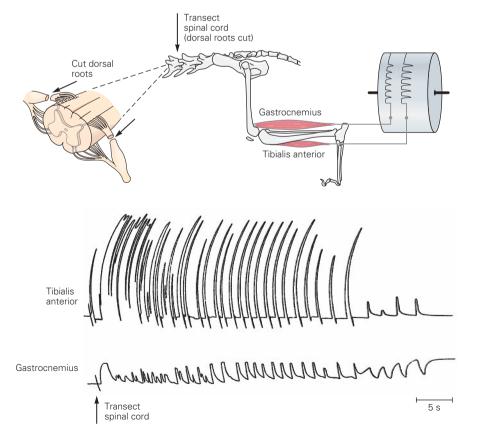

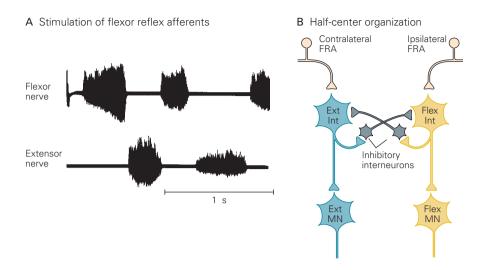

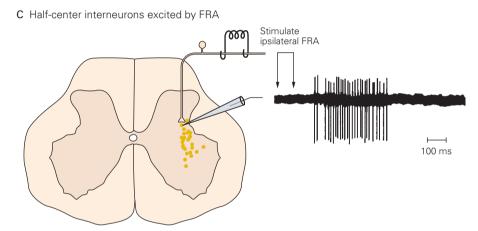

Figure 36–4 Reciprocal activity in flexor and extensor motor neurons.

A. High-threshold cutaneous and muscle afferents called flexor reflex afferents (FRA) were electrically stimulated in spinal cats treated with L-DOPA (L-dihydroxyphenylalanine) and nialamide. Brief stimulation of ipsilateral FRAs evoked a short sequence of rhythmic activity in flexor and extensor motor neurons. (Adapted, with permission, from Jankowska et al. 1967a.)

- B. Interneurons in the pathways mediating long-latency reflexes from the ipsilateral and contralateral FRAs mutually inhibit one another. This "half-center" organization of the flexor and extensor interneurons likely mediates rhythmic stepping.
- C. Stimulation of the ipsilateral FRA evokes a delayed, long-lasting burst of activity in the half-center interneurons located in the intermediate region of the gray matter. (Adapted, with permission, from Jankowska et al. 1967b.)

trains of electrical stimuli were applied to small-diameter sensory fibers from skin and muscle. These trains of stimuli evoked long-lasting bursts of activity in either flexor or extensor motor neurons, depending on whether ipsilateral or contralateral nerves were stimulated. The afferents producing these effects are collectively termed flexor reflex afferents. Additional administration of nialamide, a drug that prolongs the action of norepinephrine released in the spinal cord, often resulted in short sequences of rhythmic reciprocal activity in flexor and extensor motor neurons (Figure 36–4A).

The system of interneurons generating flexor bursts was found to inhibit the system of interneurons generating the extensor bursts, and vice versa (Figure 36–4B). This organizational feature is consistent with Graham Brown's theory that mutually inhibiting "half-centers" produce the alternating burst activity in flexor and extensor motor neurons. The interneurons mediating the burst patterns arising from stimulation of the

flexor reflex afferents have not been fully identified but they may include interneurons in the intermediate region of the gray matter in the sixth lumbar segment. Interneurons in this region produce prolonged bursts of activity in response to brief stimulation of either ipsilateral or contralateral flexor reflex afferents in spinal cats treated with L-DOPA (Figure 36–4C).

Central Pattern Generators Are Not Driven by Sensory Input

Neuronal spinal networks capable of generating rhythmic motor activity in the absence of rhythmic input from peripheral receptors are termed *central pattern generators* (Box 36–2). Largely because the mammalian nervous system is so complex, we lack detailed information on the neuronal circuitry and mechanisms for rhythm generation by central pattern generators in the mammalian spinal cord. However, we have considerable knowledge

Box 36–2 Central Pattern Generators

A central pattern generator (CPG) is a neuronal network within the central nervous system that is capable of generating a rhythmic pattern of motor activity without phasic sensory input from peripheral receptors. CPGs have been identified and analyzed in more than 50 rhythmic motor systems, including those controlling such diverse behaviors as walking, swimming, feeding, respiration, and flying.

The motor pattern generated by a CPG under experimental conditions is sometimes very similar to the motor pattern produced during natural behavior, as in lamprey swimming (see Box 36–3), but there are often significant differences. In nature the basic pattern produced by a CPG is usually modified by sensory information and signals from other regions of the central nervous system.

The rhythmic motor activity generated by CPGs depends on three factors: (1) the cellular properties of individual nerve cells within the network, (2) the properties of the synaptic junctions between neurons, and (3) the pattern of interconnections between neurons (Table 36–1). Modulatory substances, usually amines or peptides, can alter cellular and synaptic properties, thereby enabling a CPG to generate a variety of motor patterns.

The simplest CPGs contain neurons that burst spontaneously. Such endogenous bursters can drive motor neurons, and some motor neurons are themselves endogenous bursters. Bursters are common in CPGs that produce continuous rhythms, such as those for respiration. They are also found in locomotor systems. Locomotion, however, is an episodic behavior, so bursters in locomotor systems must be regulated.

Bursting is often induced by modulatory input from neurons projecting to the rhythm generating system. Neuromodulatory inputs can also alter the cellular properties of neurons so that brief depolarizations lead to maintained depolarizations (plateau potentials) that long outlast the initial depolarization. Neurons with the capacity to generate plateau potentials have been found in a large number of CPGs, and in some systems they are essential for rhythm generation.

Rhythmicity does not always depend on bursting or plateau potentials. A simple network can generate rhythmic activity if the firing of some neurons can be enhanced or reduced according to some temporal pattern. One process is postinhibitory rebound, a brief increase in excitability of a neuron after the termination of inhibitory input. Two neurons that mutually inhibit each other can oscillate in an alternating fashion if each neuron has the property of postinhibitory rebound.

Other time-dependent processes include synaptic depression, delayed onset of activity after a depolarization (delayed excitation), and differences in the time course of synaptic actions through parallel pathways connecting two neurons.

Most CPGs produce a complex temporal pattern of activation of different groups of motor neurons. Sometimes the pattern can be divided into a number of distinct phases; even within a phase the activity of different motor neurons can be timed separately. The sequencing of activity in motor neurons is regulated by a number of mechanisms. Perhaps the simplest mechanism is mutual inhibition; interneurons that fire out of phase with each other are usually reciprocally coupled by inhibitory connections

Another mechanism is the rate of recovery from inhibition, which can influence the relative time of onset of activity in two neurons simultaneously released from inhibition. Finally, mutual excitation is an important mechanism for establishing synchronous firing in a group of neurons. Electrical synapses are often employed for mutual excitation, particularly when a rapid high-intensity burst within a group of neurons is needed.

Table 36-1 Building Blocks of Rhythm-Generating Networks

Cellular properties	Synaptic properties	Patterns of connection
Threshold	Sign	Reciprocal inhibition
Frequency-current relationship	Strength	Recurrent inhibition
Spike frequency adaptation	Time course	Parallel excitation and inhibition
Post-burst hyperpolarization	Transmission (electrical, chemical)	Mutual excitation
Delayed excitation	Release mechanisms (spike, graded signal)	
Post-inhibitory rebound		
Plateau potentials	Multicomponent postsynaptic potentials	
Bursting (endogenous, conditional)	Facilitation/depression (short-term, long-term)	

about the cellular, synaptic, and network properties of central pattern generators in invertebrates and lower vertebrates, which have less complex nervous systems than mammals. For example, the analysis by Sten Grillner of the central pattern generator controlling swimming in the lamprey has provided considerable insight into the mechanisms of rhythm generation in vertebrate motor systems (Box 36–3).

Recent studies using the spinal cord of the neonatal rat have identified several classes of rhythmically active interneurons and demonstrated that some of these interneurons can generate sustained membrane

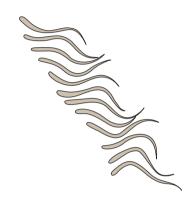

Box 36–3 Lamprey Swimming

One of the best-analyzed central pattern generators is that for lamprey swimming. Lampreys swim by alternating muscle contrations on the two sides of each body segment (Figure 36–5). Each segment contains a neural network capable of generating rhythmic, alternating activity in motor neurons on the two sides (Figure 36–6).

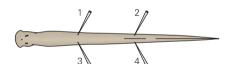

On each side of the network excitatory interneurons drive the motor neurons and two classes of inhibitory interneurons, commissural and local. The axons of the commissural interneurons cross the midline and inhibit all neurons in the contralateral half of the network, ensuring that when muscles on one side of the network are active, muscles on the other side are silent. The local inhibitory interneurons inhibit the commissural interneurons on the same side.

A number of cellular and synaptic mechanisms are involved in the initiation and termination of activity on one side of the network. One important mechanism in the initiation of activity is the opening of NMDA-type glutamate receptor-channels. Once the inhibition from contralateral commissural interneurons is terminated, the NMDA-type receptor-channels in all ipsilateral neurons are opened by a brief depolarization (post-inhibitory rebound) and the voltage-dependency of the channels leads to plateau potentials.

Figure 36–5 The lamprey swims by means of a wave of muscle contractions traveling down one side of the body 180 degrees out of phase with a similar traveling wave on the opposite side. This pattern is evident in electromyogram recordings from four locations along the animal during normal swimming. A similar pattern is recorded from four spinal roots in an isolated cord. (Adapted, with permission, from Grillner et al. 1987.)

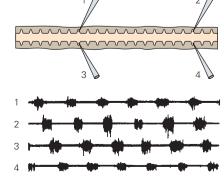

Rhythm in intact animal

Rhythm in isolated cord

depolarizations (*plateau potentials*) in response to weak synaptic input. Because this active membrane property is known to be important for rhythm generation in simpler systems, it is likely that it also contributes to rhythm generation in the mammalian spinal cord.

Spinal Networks Can Generate Complex Locomotor Patterns

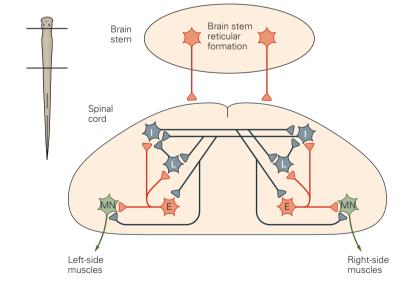

The locomotor patterns generated in deafferented or immobilized spinal animals are generally much simpler than normal stepping patterns. Usually they

Activation of low-voltage Ca^{2+} channels further strengthens the depolarization. The influx of Ca^{2+} through these channels and the NMDA-type receptor-channels activates calcium-dependent K^+ channels. The resultant increase in K^+ conductance terminates the plateau potentials and so contributes to the termination of activity.

Two additional mechanisms contribute to the termination of activity in each half of the network. One is

a progressive decline in the discharge rate of the neurons resulting from the summation of slow afterhyperpolarizations. The other is delayed excitation of the local inhibitory interneurons. When excited, these interneurons inhibit the commissural interneurons (Figure 36–6), thereby removing inhibition from the contralateral half of the network and enabling it to become active.

Figure 36–6 Each body segment of the lamprey contains a neuronal network responsible for the motor pattern in that segment. Activity in each segmental network is initiated by activity in glutamatergic axons descending from the brain stem reticular formation. The reticulospinal neurons increase the excitability of all neurons in a segmental network by activation of both NMDA-type and non-NMDA-type glutamate receptors. On each side of the network excitatory interneurons (E) drive the motor neurons (MN) and two classes of inhibitory interneurons, commissural (I) and local (L). (Adapted, with permission, from Grillner et al. 1995.)

squeezed. The patterns are radically different. (Sart, sartorius; RF, rectus femoris; ST, semitendinosus.) (Adapted, with permission, from Perret and Cabelguen 1980.)

D. This schematic description of a locomotor pattern generator is based on recent studies on fictive locomotion in decerebrate cats. The basic rhythmic pattern is produced by mutually inhibiting flexor and extensor half-centers. The interneurons of these half-centers drive the motor neurons through an intermediate system of interneurons (patterning network) that control the timing of activation of different classes of motor neurons. Descending signals, drugs, or afferent signals can modify the temporal motor activity pattern by altering the functioning of interneurons in the patterning network. (Adapted, with permission, from Rybak et al. 2006.)

consist of alternating bursts of activity in flexor and extensor motor neurons (Figure 36–7A). More complex locomotor patterns can be generated in immobilized spinal animals after a period of training or through the application of additional drugs such as 4-aminopyridine. Moreover, in decerebrate animals elaborate locomotor patterns can be produced in hind

limb motor neurons after deafferentation (Figure 36–7B). These patterns resemble those recorded in the same animals before deafferentation. Finally, a variety of patterns can be generated in immobilized decerebrate animals, and these patterns can be altered significantly by changing the level of tonic sensory input (Figure 36–7C).

From these observations it is clear that the spinal pattern-generating network for each leg can produce a variety of motor patterns. Which pattern is generated depends on many factors, such as the supraspinal and tonic sensory inputs to the spinal pattern generators as well as the drugs used to experimentally initiate rhythmicity. This functional flexibility may be explained by a scheme in which mutually inhibiting half-centers produce the basic rhythmicity and establish a general pattern of reciprocal activity in flexor and extensor motor neurons, whereas the details of the temporal pattern are established by a network of interneurons (the patterning network) connecting the half-centers and motor neurons (Figure 36–7D).

Sensory Input from Moving Limbs Regulates Stepping

Although normal walking is automatic, it is not necessarily stereotyped. Mammals constantly use sensory input to adjust their stepping patterns to variations in terrain and to anticipated and unexpected conditions. This input is provided predominantly by three sensory systems: the visual, vestibular, and somatosensory systems. Proprioceptors in muscles and joints provide information about body movements and are involved in the automatic regulation of stepping. Cutaneous receptors in the skin, sometimes referred to as exteroceptors, adjust stepping to external stimuli and can also provide important feedback about body movements.

Proprioception Regulates the Timing and Amplitude of Stepping

One of the clearest indications that somatosensory signals from the limbs regulate the step cycle is that the rate of stepping in spinal and decerebrate cats matches the speed of the motorized treadmill belt on which they tread. Specifically, afferent input regulates the duration of the stance phase. As the stepping rate increases, the stance phase becomes shorter while the swing phase remains relatively constant. This observation suggests that some form of sensory input signals the end of stance and thus leads to the initiation of swing.

Sherrington was the first to propose that proprioceptors in muscles acting at the hip are primarily responsible for regulating the stance phase. He noticed that rapid extension at the hip joint, but not at the knee and ankle joints, led to contractions in the hip flexor muscles of chronic spinal cats and dogs. More recent studies have found that preventing hip extension in a limb

suppresses stepping in that limb, whereas rhythmically moving the hip can entrain the locomotor rhythm, that is, cause the timing of the neural output to match the rhythm of the externally imposed movements.

During entrainment a burst of activity in hip flexor motor neurons is initiated in synchrony with hip extension (Figure 36–8A). The afferent fibers that signal hip angle for swing initiation arise from muscle spindles in the hip flexor muscles. In decerebrate animals stretching these muscles to mimic the lengthening that occurs at the end of the stance phase inhibits the extensor half-center and thus facilitates the initiation of burst activity in flexor motor neurons during walking (Figure 36–8B).

Other important proprioceptive signals for regulating the step cycle arise from proprioceptors in extensor muscles. Electrical stimulation of sensory fibers from Golgi tendon organs and muscle spindles prolongs the stance phase, often delaying the onset of swing until the stimulus has ended (Figure 36–9A). Sensory fibers from both types of receptors are active during stance.

The intensity of the signal from the Golgi tendon organs is related to the load carried by the leg. Golgi tendon organs have an excitatory action on ankle extensor motor neurons during walking but an inhibitory action when the body is at rest (see Chapter 35). The functional consequence of this reflex reversal is that the swing phase is not initiated until the extensor muscles are unloaded and the forces exerted by these muscles are low, as signaled by a decrease in activity from the Golgi tendon organs. Unloading of extensor muscles normally occurs near the end of stance, when the animal's weight is borne by the other legs and the extensor muscles are shortened and thus unable to produce high forces.

In addition to regulating the transition from stance to swing, proprioceptive information from muscle spindles and Golgi tendon organs contributes significantly to the generation of burst activity in extensor motor neurons. Reducing this sensory input in cats diminishes the level of extensor activity by more than half; in humans it has been estimated that up to 30% of the activity of ankle extensor motor neurons is caused by feedback from the extensor muscles.

At least three excitatory pathways transmit sensory information from extensor muscles to extensor motor neurons: a monosynaptic pathway from primary muscle spindles (group Ia afferents), a disynaptic pathway from primary muscle spindles and Golgi tendon organs (group Ia and Ib afferents), and a polysynaptic pathway from primary muscle spindles and Golgi tendon organs that includes interneurons in the central pattern generator (Figure 36–9B). The continuous regulation of the

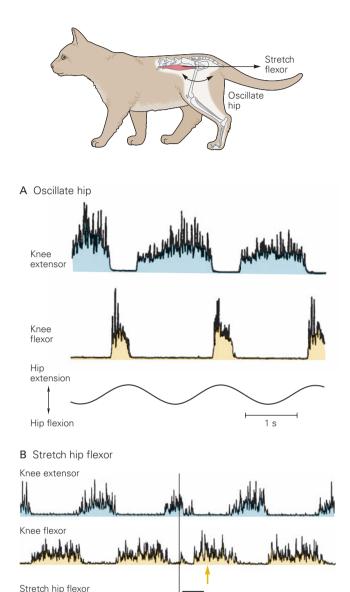

Figure 36–8 Information on hip extension controls the transition from stance to swing.

500 ms

A. In an immobilized decerebrate cat oscillating movement around the hip joint entrains the fictive locomotor pattern in knee extensor and flexor motor neurons. The flexor bursts, corresponding to the swing phase, are generated when the hip is extended. (Adapted, with permission, from Kriellaars et al. 1994.)

B. In a walking decerebrate cat stretching of the hip flexor muscle (iliopsoas) inhibits knee extensor activity allowing knee flexor activity to begin earlier. The **arrow** in the knee-flexor record indicates the expected onset of knee flexor activity had the hip flexor muscle not been stretched. Activation of sensory fibers from muscle spindles in the hip flexor muscle is responsible for this effect. (Adapted, with permission, from Hiebert et al. 1996.)

level of extensor activity by proprioceptive feedback presumably allows automatic adjustment of force and length in extensor muscles in response to unexpected unloading and loading of the leg.

Sensory Input from the Skin Allows Stepping to Adjust to Unexpected Obstacles

Sensory receptors in the skin have a powerful influence on the central pattern generator for walking. One important function of these receptors is to detect obstacles and adjust stepping movements to avoid them. A well-studied example is the stumbling-corrective reaction in cats. A mild mechanical stimulus applied to the dorsal part of the paw during the swing phase produces excitation of flexor motor neurons and inhibition of extensor motor neurons, leading to rapid flexion of the paw away from the stimulus and elevation of the leg in an attempt to step over the object. Because this corrective response is readily observed in spinal cats, it must be produced to a large extent by circuits entirely contained within the spinal cord.

One of the interesting features of the stumbling-corrective reaction is that corrective flexion movements are produced only if the paw is stimulated during the swing phase. An identical stimulus applied during the stance phase produces the opposite response, excitation of extensor muscles that reinforces the ongoing extensor activity. This extensor action is appropriate; if a flexion reflex were produced during the stance phase the animal might collapse because it is being supported by the limb. This is an example of a *phase-dependent reflex reversal:* The same stimulus excites one group of motor neurons during one phase of locomotion but activates the antagonist motor neurons during another phase.

Descending Pathways Are Necessary for Initiation and Adaptive Control of Stepping

Although the basic motor pattern for stepping is generated in the spinal cord, fine control of stepping movements involves many regions of the brain, including the motor cortex, cerebellum, and various sites within the brain stem. Many neurons in each of these regions are rhythmically active during locomotor activity and hence participate in the production of the normal motor pattern. Each region, however, plays a different role in the regulation of locomotor function.

Supraspinal regulation of stepping can be divided into three functional systems. One activates the spinal locomotor system, initiates walking, and controls the

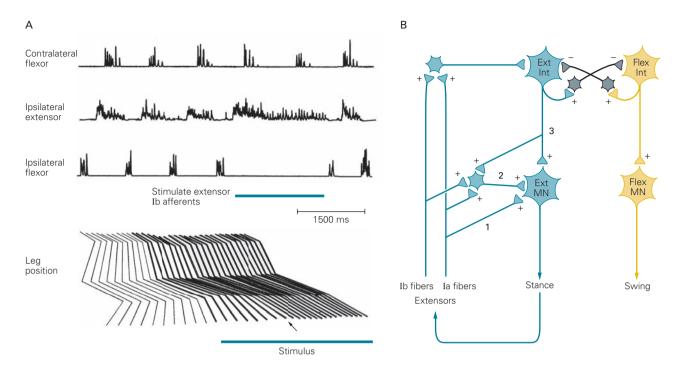

Figure 36–9 The swing phase of walking is initiated by sensory feedback from extensor muscles.

A. In a decerebrate cat electrical stimulation of group I sensory fibers from ankle extensor muscles inhibits bursting in ipsilateral flexors and prolongs the burst in the ipsilateral extensors during walking. The timing of contralateral flexor activity is not altered. Stimulating group I fibers from the extensors prevents initiation of the swing phase, as can be seen in the position of the leg during the time the fibers were stimulated. The **arrow** shows the point at which the swing phase would normally have occurred had the extensor afferents not been stimulated. (Adapted, with permission, from Whelan, Hiebert, and Pearson 1995.)

B. Afferent pathway from extensor muscles regulating stance. Two mutually inhibiting groups of extensor and flexor interneurons constitute a central pattern generator. Feedback from extensor muscles increases the level of activity in extensor motor neurons during stance and maintains extensor activity when the extensor muscles are loaded. The feedback is relayed through three excitatory (+) pathways: monosynaptic connections from la fibers to extensor motor neurons (1); disynaptic connections from la and lb fibers (2); and a polysynaptic excitatory pathway through the extensor interneurons (3).

overall speed of locomotion; another refines the motor pattern in response to feedback from the limbs; and the third visually guides limb movement (Figure 36–10).

Pathways from the Brain Stem Initiate Walking and Control Its Speed

In their seminal studies of decerebrate cats, Mark Shik, Fidor Severin, and Grigori Orlovsky found that tonic electrical stimulation of the mesencephalic locomotor region initiates stepping when decerebrate animals are placed on a treadmill. The mesencephalic locomotor region is situated approximately 6 mm ventral to the inferior colliculus (Figure 36–11A), close to the cuneiform nucleus. The rhythm of the locomotor pattern is related only to the intensity of electrical stimulation, not

to its pattern. Weak stimulation produces a slow walking gait, which accelerates as the intensity increases; progressively stronger stimulation produces trotting and finally galloping (Figure 36–11B).

The transition from trotting to galloping is especially interesting for it involves a shift from an out-of-phase relationship between left and right legs in trotting to an in-phase relationship in galloping. This shift in interlimb coordination is also observed in spinal cats walking on a motorized treadmill as the speed is increased. Therefore it is most likely implemented by local circuits in the spinal cord.

In addition to the mesencephalic locomotor region, several other motor regions of the brain can produce locomotion when stimulated electrically. These include a subthalamic locomotor region and a nucleus

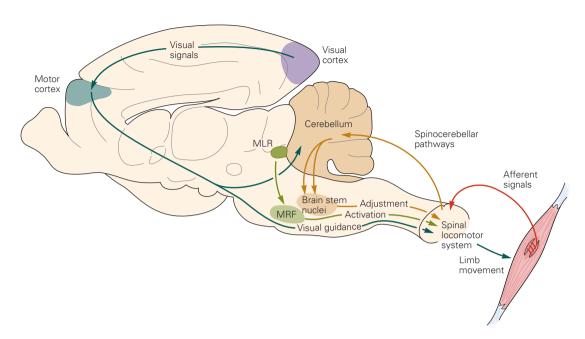

Figure 36–10 The brain stem and motor cortex control locomotion. The spinal locomotor system is activated by signals from the mesencephalic locomotor region (MLR) relayed by neurons in the medial reticular formation (MRF). The cerebellum receives signals from both peripheral receptors and spinal

central pattern generators and adjusts the locomotor pattern through connections in brain stem nuclei. Visual information conveyed to the motor cortex can also modify stepping movements.

in the pontine reticular formation (pontine peduncular nucleus). How these different brain stem regions interact in the normal control of locomotion is not yet known.

How are signals from locomotor regions of the brain stem transmitted to patterning networks in the spinal cord? Because application of adrenergic drugs is often sufficient to initiate stepping in acute spinal animals, an early hypothesis was that the initiation and maintenance of locomotor activity depends on activity in the descending noradrenergic pathway from the locus ceruleus or the descending serotonergic pathway from the raphe nucleus. However, because locomotor activity can be evoked after depletion of norepinephrine and serotonin, neither of these aminergic pathways is essential for locomotion. The current view is that these transmitters are modulators that regulate the magnitude and timing of motor neuron activity in the locomotor networks in the spinal cord. Although adrenergic drugs can initiate stepping movements in the spinal animal, aminergic neurons may not serve this function in nature.

Clues about the identity of the descending system that initiates locomotor activity came first from studies on the neonatal rat and lamprey. Administration of glutamate receptor agonists to the isolated spinal cord was found to initiate locomotor activity. In decerebrate cats administration of agonists to the NMDA-type glutamate receptors in the spinal cord initiates locomotor activity similar to that evoked by electrical stimulation of the mesencephalic locomotor region. The application of glutamate receptor antagonists prevents this response. These observations suggest that glutamatergic pathways are involved in initiating locomotor activity.

Considerable research has been devoted to identifying the origin and course of the descending pathways that initiate locomotor activity. The central pattern generators in the spinal cord cannot be directly activated by neurons in the nuclei near the mesencephalic locomotor region, for the axons of these neurons do not descend directly to the cord. Instead, the mesencephalic motor neurons form connections with neurons in the medullary reticular formation, whose axons descend in the ventrolateral region of the spinal cord (Figure 36–11A). These neurons are excited by stimulation of the mesencephalic locomotor region, and transection of their axons in the ventrolateral funiculus of the spinal cord prevents stimulation of the mesencephalic locomotor region from initiating locomotor activity. Thus current evidence indicates that the signals that activate locomotion and control its speed are transmitted to the spinal cord by glutamatergic neurons with axons that travel in ventral reticulospinal pathways.

The Cerebellum Fine-Tunes Locomotor Patterns by Regulating the Timing and Intensity of Descending Signals

Damage to the cerebellum results in marked abnormalities in locomotor movements, including a widened base

of support, impaired coordination of joints, and abnormal coupling between limbs during stepping. These symptoms are called *ataxia* (see Chapter 42). Ataxic walking resembles a drunken gait. Because ataxic gait is apparent in patients with cerebellar lesions even when they are walking on level surfaces, we can conclude that the cerebellum is involved in regulating all stepping movements.

The cerebellum receives sensory information about the actual stepping movements as well as information on the state of the central pattern generators through

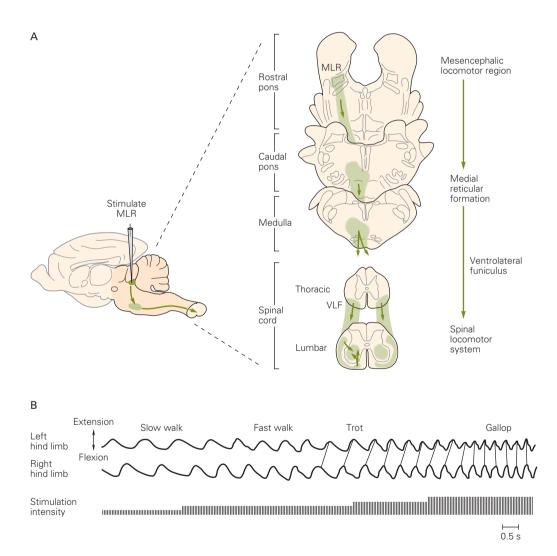

Figure 36–11 The mesencephalic locomotor region modifies stepping patterns.

A. Stimulation of the mesencephalic locomotor region (MLR) excites interneurons in the medial reticular formation whose axons descend in the ventrolateral funiculus (VLF) to the spinal locomotor system. (Adapted, with permission, from Mori et al. 1992.)

B. When the strength of stimulation of the mesencephalic locomotor region in a decerebrate cat walking on a treadmill is gradually increased, the gait and rate of stepping change from slow walking to trotting and finally to galloping. As the cat progresses from trotting to galloping, the hind limbs shift from alternating to simultaneous flexion and extension.

two ascending pathways. For the hind legs of the cat these are the dorsal and ventral spinocerebellar tracts. Neurons in the dorsal tract are strongly activated by numerous leg proprioceptors and thus provide the cerebellum with detailed information about the mechanical state of the hind legs. In contrast, neurons in the ventral tract are activated primarily by interneurons in the central pattern generator, thus providing the cerebellum with information about the state of the spinal locomotor network. The cerebellum also receives input from the motor cortex and other forebrain regions related to locomotor function.

It is thought that the cerebellum compares actual movements of the legs—proprioceptive signals in the dorsal spinocerebellar tract—with intended movements—the central commands conveyed in the ventral spinocerebellar tract and collaterals of corticospinal tract neurons. When these two types of information differ, representing an error, the cerebellum computes corrective signals and sends these to various brain stem nuclei.

During walking the cerebellum influences several brain stem nuclei, including the vestibular nuclei, red nucleus, and nuclei in the medullary reticular formation. The signals from the cerebellum to the vestibular nuclei during walking are likely used to regulate balance by integrating information about the position and movement of the head derived from the vestibular system with proprioceptive information about movements of the legs.

The Motor Cortex Uses Visual Information to Control Precise Stepping Movements

Normal walking is often guided by vision, and the motor cortex is essential for visually guided movement. Experimental lesions of the motor cortex do not prevent animals from walking on a smooth floor or even on smooth inclines, but they severely impair tasks requiring a high degree of visuomotor coordination, such as walking on the rungs of a horizontal ladder, stepping over a series of barriers, and stepping over single objects placed on a treadmill belt. Such "skilled walking" is associated with considerable modulation in the activity of a large number of neurons in the motor cortex (Figure 36–12).

Many of these neurons project directly to the spinal cord and thus may regulate the activity of interneurons in the central pattern generator for locomotion, thereby adapting the timing and magnitude of motor activity to a specific task. Electrical stimulation of either the motor cortex or the corticospinal tract in normal walking cats influences the timing of locomotor activity;

these effects are generally stronger than those elicited by stimulation of brain stem regions.

Planning and Coordination of Visually Guided Movements Involves the Posterior Parietal Cortex

When humans and animals approach an obstacle in their pathway they must adjust their stepping to either move around the obstacle or step over it. These adjustments begin two or three steps before the obstacle is reached. Recent studies by Trevor Drew and his colleagues have shown that the posterior parietal cortex has an essential role in planning these adjustments.

Small lesions in this region cause walking cats to misplace the positioning of their paws as they approach an obstacle, and to increase the probability that one or more legs contact the obstacle as they step over it. Recordings in the parietal cortex have identified sets of neurons that could be involved in the planning and coordination of stepping movements. Some neurons increase their activity as an animal approaches an obstacle, whereas others maintain their activity when an obstacle passes under the animal (Figure 36–13).

Visual information about the size and location of an obstacle is registered as the obstacle is approached, and this information is stored in working memory, a form of short-term memory, to guide the legs. In humans obstructing vision one stride before an obstacle is encountered does not influence foot clearance over the obstacle. In quadrupeds, however, such working memory is necessary because an obstacle is no longer within the visual field by the time the hind legs are stepping over it.

Many of the features of the working memory for guiding the legs have recently been established in cats. The main features are that the forelegs must step over the obstacle in order for the memory to be established, the trajectories of the hind legs are scaled appropriately for the height of the obstacle and for the relative positions of the hind paws and the obstacle, and the memory persists for many minutes without declining.

The neurobiological mechanisms underlying this form of memory remain to be established, but the persistence of the memory appears to depend upon neuronal systems in the posterior parietal cortex. With bilateral lesions of the medial posterior parietal cortex the memory is completely abolished after a few seconds (Figure 36–14). Complementing this observation is the recent identification by Trevor Drew and colleagues of neurons in the posterior parietal cortex whose activity is elevated while the cat straddles an obstacle with the forelegs on one side and the hind legs on the other side.

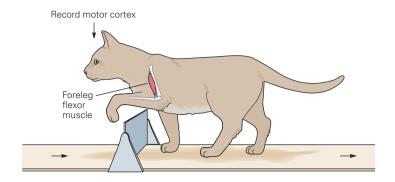

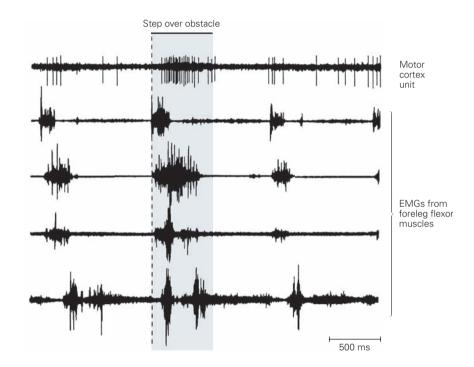

Figure 36–12 Stepping movements are adapted by visual input in the motor cortex. When a normal cat steps over a visible object fixed to the belt of a treadmill, neurons in the motor cortex increase in activity. This increase in cortical activity is associated with enhanced activity in foreleg muscles, as seen in the electromyograms (EMG). (Adapted, with permission, from Drew 1988.)

Human Walking May Involve Spinal Pattern Generators

Unlike spinal cats and other quadrupeds, humans with spinal cord transection generally are not able to walk spontaneously. Nevertheless, some observations of patients with spinal cord injury parallel the findings from studies of spinal cats. In one striking case a patient with nearly complete transection of the spinal cord showed uncontrollable, spontaneous, rhythmic movements of the legs when the hips were extended. This behavior closely parallels the rhythmic stepping movements in chronic spinal cats. In another study on a few patients with severe spinal cord injury, stepping on a treadmill was improved by clonidine, a drug influencing biogenic amines.

Compelling evidence for the existence of spinal rhythm-generating networks in humans comes from studies of development. Human infants make rhythmic stepping movements immediately after birth if held upright and moved over a horizontal surface. This strongly suggests that some of the basic neuronal circuits for locomotion are innate. Because stepping can occur in infants who lack cerebral hemispheres (anencephaly), these circuits must be located at or below the brain stem, perhaps entirely within the spinal cord.

During the first year of life, as automatic stepping is transformed into functional walking, these basic circuits are thought to be brought under supraspinal control in two ways. First, the infant develops voluntary control of locomotion. From what we know about the neuronal mechanisms in the cat, this ability could depend on the

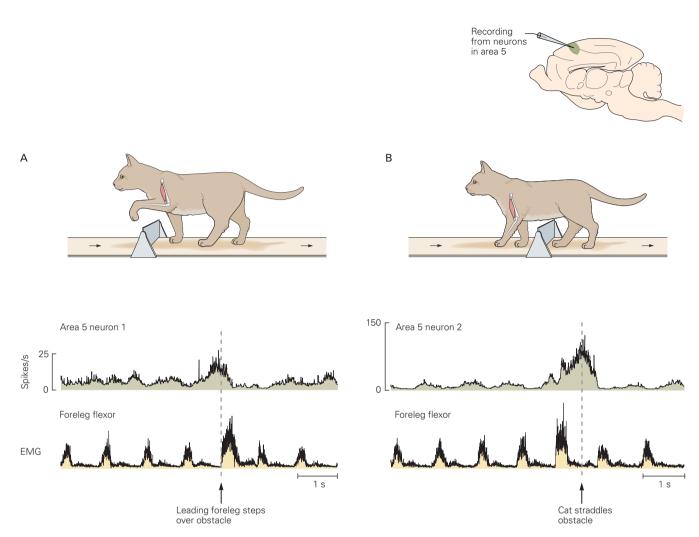

Figure 36–13 Neurons in area 5 of the posterior parietal cortex of the cat are involved in visuomotor transformations of walking. (Adapted, with permission, from Drew et al. 2008.)

A. The activity of a neuron increases as the animal approaches an obstacle and then declines the instant the leading foreleg begins to step over the obstacle.

B. Activity in a different neuron increases after the leading foreleg begins to step over an obstacle and is maximally active when the cat straddles the obstacle.

maturation of reticulospinal pathways and regions of the brain stem that project to reticulospinal neurons, such as the mesencephalic locomotor region. Second, the stepping pattern gradually develops from a primitive flexion-extension pattern that generates little effective forward movement to the mature pattern of complex movements. Again based on studies of cats, it is plausible that this adaptation reflects maturation of descending systems that originate in the motor cortex and brain stem nuclei and which are modulated by the cerebellum.

Parallels between human and quadrupedal walking have also been found in patients trained after spinal

cord injury. Daily training restores stepping in spinal cats and improves stepping in patients with chronic spinal injuries. In patients with complete spinal cord injury motor patterns evoked in response to rhythmic leg movements can also be modified by daily therapy (Box 36–4). Thus the spinal networks for locomotion in humans and cats can adapt.

In light of these findings there is reason to believe that human walking relies on the same general principles of neuronal organization as quadrupedal walking: Intrinsic oscillatory networks are activated and modulated by other brain structures and by afferent input. Nevertheless, human bipedal locomotion differs from most animal locomotion in that it places significantly greater demands on descending systems that control balance during walking. Indeed, maturation of the systems that control balance and stepping patterns is necessary for the infant to begin walking independently at the end of the first year. In contrast, horses can stand and walk

within hours after birth. It is therefore likely that the locomotor spinal networks in humans are more dependent on supraspinal centers than those in quadrupeds. This dependence may explain in part the relatively few observations of spontaneous stepping movements in humans with complete spinal cord injury.

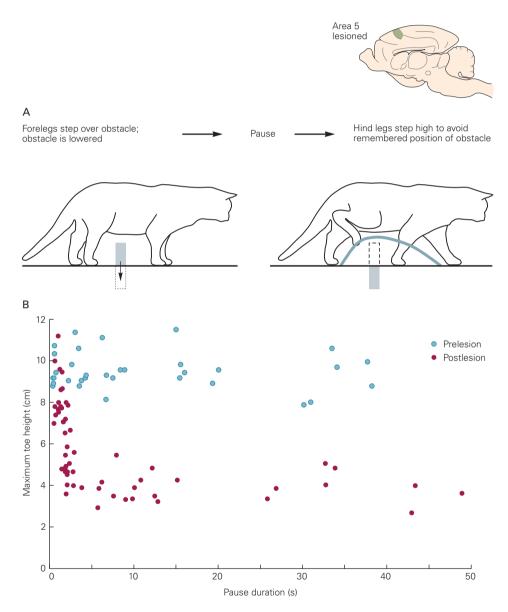

Figure 36–14 A walking cat's working memory of an obstacle is impaired following bilateral lesions of area 5 in the posterior parietal cortex.

A. A normal animal walks forward, steps over an obstacle, and pauses. While the animal pauses, the obstacle is removed. When walking resumes, the hind legs step high to avoid the remembered obstacle. The **blue line** traces the elevated trajectory of one toe.

B. The maximum toe heights of the hind legs are plotted against pause duration before and a few days after bilateral lesions of area 5 of posterior parietal cortex. The impairment of memory is indicated by the decline in maximum toe height for pause durations greater than a few seconds. (Adapted, with permission, from McVea et al. 2009.)

Box 36-4 Improving Walking After Spinal Cord Injury

Every year approximately 11,000 people in the United States injure their spinal cords, and for many this results in permanent loss of sensation, movement, and autonomic function. The devastating loss of functional abilities, together with the enormous cost of treatment and care, creates an urgent need for effective methods to repair the injured spinal cord and to facilitate functional recovery.

Over the past decade considerable progress has been made in animal research aimed at repairing the axons of damaged neurons in the spinal cord and promoting the regeneration of severed axons through and beyond the site of injury. In many instances the regeneration of axons has been associated with modest recovery of locomotor function. However, none of these strategies has reached the point where it can be confidently used in humans with spinal cord injury.

Therefore, rehabilitative training is the preferred treatment for patients with spinal cord injury. One

especially successful technique for enhancing walking in patients with partial damage to the spinal cord is repetitive, weight-supported stepping on a treadmill (Figure 36–15). This technique is firmly based on the observation that spinal cats can be trained to step with their hind leg on a moving treadmill (see Box 36–1).

For humans partial support of the body weight through a harness system is critical to the success of training; presumably it facilitates the training of spinal cord circuits by reducing the requirements for supraspinal control of posture and balance.

Although the neural basis for the improvement in locomotor function with treadmill training has not been established, it is thought to depend on synaptic plasticity in local spinal circuits as well as successful transmission of at least some command signals from the brain through preserved descending pathways.

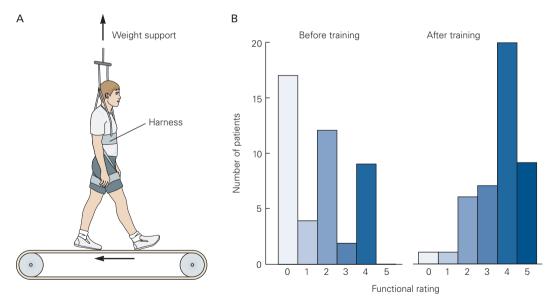

Figure 36–15 Treadmill training improves locomotor function in patients with partial spinal cord injury. (Adapted, with permission, from Wernig et al. 1995.)

A. A patient is partially supported on a moving treadmill by a harness, and stepping movements are assisted by therapists.

B. Locomotor function improved in 44 patients with chronic spinal cord injury after they received daily training lasting from 3 to 20 weeks. The functional rating ranges from 0 (unable to stand or walk) to 5 (walking without devices for more than five steps).

An Overall View

Locomotion in mammals typically involves rhythmic movements of the body and one or more limbs. These movements depend on precise regulation of the timing and strength of contractions in numerous muscles. Local spinal circuits, known as central pattern generators, can produce the basic motor pattern for locomotion even without sensory information from peripheral receptors. Numerous examples of central pattern generators have been analyzed at the cellular level, and it is clear that a wide variety of cellular, synaptic, and network properties are involved in these local networks.

Central pattern generators are extremely flexible; their cellular and synaptic properties can be modified by modulatory signals at chemical synapses. Their functioning depends on how they are activated and the pattern of afferent input they receive.

Modern research on mammalian locomotion dates from the 1960s, when two important experimental animal preparations were introduced. In the decerebrate animal stepping can be initiated by electrical stimulation of a site in the brain stem, the mesencephalic locomotor region. In the spinal preparation centrally generated locomotor activity can be evoked after the administration of adrenergic drugs.

Using these preparations, investigators have confirmed and extended fundamental observations made at the beginning of the 20th century, namely that the basic rhythm for locomotion is generated centrally in spinal networks, that the transition from stance to swing is regulated by afferent signals from leg flexor and extensor muscles, and that descending signals from the brain regulate the intensity of locomotion and modify stepping movements according to the terrain on which the animal is walking.

An Overall View

".... The physiology of movements is basically a study of the purposive activity of the nervous system as a whole."

- Gelfand et al., 1966

NE OF THE MAIN FUNCTIONS OF THE BRAIN is to direct the body's purposeful interaction with the environment. Understanding how the brain

fulfils this role is one of the great challenges in neural science. Because large areas of the cerebral cortex are implicated in voluntary motor control, the study of the cortical control of voluntary movement provides important insights into the functional organization of the cerebral cortex as a whole.

Evolution has endowed mammals with adaptive neural circuitry that allows them to interact in sophisticated ways with the complex environments in which they live. Adaptive patterning of voluntary movements gives mammals a distinct advantage in locating food, finding mates, and avoiding predators, all of which enhance the survival potential of the individual and a species.

The ability to use fingers, hands, and arms in voluntary actions independent of locomotion further helps primates, and especially humans, exploit their environment. Most animals must search their environment for food when hungry. In contrast, humans can also "forage" by using their hands to cook a meal or simply punch a few buttons on a telephone and order takeout. The central neural circuits responsible for such nonlocomotor behavior emerged from and remain intimately associated with the phylogenetically older circuits that control the forelimb during locomotor behaviors.

In this and the following chapter we focus on the control of voluntary movements of the hand and arm in primates. In this chapter we describe the cortical networks that control voluntary movement, particularly the role of the primary motor cortex in the generation of motor commands. In the next chapter we address broader questions about cortical control of voluntary motor behavior, in particular how the cerebral cortex

organizes the stream of incoming sensory information to guide voluntary movement.

Voluntary movements differ from reflexes and basic locomotor rhythms in several important ways. By definition they are intentional—they are initiated by an internal decision to act—whereas reflexes are automatically triggered by external stimuli. Even when a voluntary action is directed toward an object, such as reaching for a cup, the cause of action is not the object but an internal decision to interact with the object. The presence of the object provides only the opportunity for acting. Voluntary actions involve choices between alternatives, including the choice not to act. Furthermore, they are organized to achieve some goal in the near or distant future.

Voluntary movements often have a labile, context-dependent association with sensory inputs. The same object can evoke different voluntary actions or no response at all depending on the context in which it appears. That is, the neural circuits controlling voluntary behavior are able to differentiate between an object's physical properties and its behavioral salience.

The nature and effectiveness of voluntary movements often improve with experience. The motor system can learn new behavioral strategies or new reactions to familiar stimuli to improve behavioral outcomes, and it can learn new skills to cope with predictable variations and perturbations of the environment.

Thus the neural control of voluntary movement involves far more than simply generating a particular pattern of muscle activity. It also involves processes that are usually considered to be more sensory, perceptual, and cognitive in nature. As we shall see, these processes are not rigidly compartmentalized into different neural structures or neural populations.

Motor Functions Are Localized within the Cerebral Cortex

For centuries it was believed that the human cerebral cortex was responsible for only higher-order, conscious mental functions. In the middle of the 19th century the English neurologist John Hughlings Jackson made the controversial proposal that a specific part of the cerebral cortex anterior to the central sulcus has a causal role in movement. He reached this conclusion from treating patients with epileptic seizures that were characterized by repeated spasmodic involuntary movements that sometimes resembled fragments of purposive voluntary actions.

During each episode the seizures always spread to different body parts in a fixed temporal sequence that varied from patient to patient, a pattern called Jacksonian march. Jackson concluded that paroxysmal neural activity generated by epileptic foci located near the central sulcus caused the involuntary seizures. He speculated that the progression of seizures across the body resulted from the spread of paroxysmal activity across small clusters of neurons lying along the central sulcus, each of which controlled movement of a different body part. Jackson's proposal that a discrete cortical region is involved in the control of movement was a strong argument for the localization of different functions in distinct parts of the cerebral cortex. His observations, along with contemporaneous studies by Pierre Paul Broca and Karl Wernicke on the language deficits resulting from specific cortical lesions, laid the foundation for the modern scientific study of cortical function.

It was not until later in the 19th century, however, when improved anesthesia and aseptic surgical techniques allowed direct experimental study of the cerebral cortex in live subjects, that conclusive experimental evidence for a discrete region of the cerebral cortex devoted to motor function was possible. Gustav Fritsch and Eduard Hitzig in Berlin and David Ferrier in England showed that electrical stimulation of the surface of a limited area of cortex of different surgically anesthetized mammals evoked movements of parts of the contralateral body. The electric currents needed to evoke movements were lowest in a narrow strip along the rostral bank of the central sulcus.

Their experiments demonstrated that, even within this strip of tissue, discrete sites contained neurons with distinctive functions. Stimulation of adjacent sites evoked movements in adjacent body parts, starting with the foot, leg, and tail medially, and proceeding to the trunk, arm, hand, face, mouth, and tongue more laterally. When they lesioned a cortical site at which stimulation had evoked movements of a part of the body, motor control of that body part was perturbed or lost after the animal recovered from surgery. These early experiments showed that the motor strip contains an orderly motor map of the contralateral body and that the integrity of the motor map is necessary for voluntary control of the corresponding body parts.

In the first half of the 20th century more focal electrical stimulation allowed the motor map to be defined in greater detail. Clinton Woolsey and his colleagues tested the functional organization of the motor cortex in several species of mammals, whereas Wilder Penfield and co-workers tested discrete sites in human neurosurgical patients (Figure 37–1). Their findings

A Macaque monkey

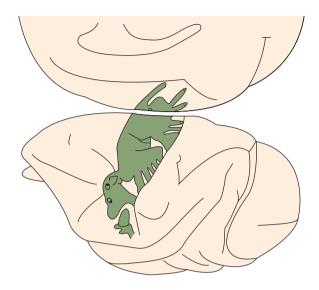

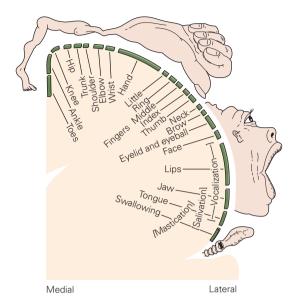

Figure 37–1 The motor cortex contains a topographic map of motor output to different parts of the body.

A. Studies by Clinton Woolsey and colleagues confirmed that the representation of different body parts in the monkey follows an orderly plan: Motor output to the foot and leg is medial, whereas the arm, face, and mouth areas are more lateral. The areas of cortex controlling the foot, hand, and mouth are much larger than the regions controlling other parts of the body.

B. Wilder Penfield and colleagues showed that the human motor cortex motor map has the same general mediolateral

B Human

organization as in the monkey. However, the areas controlling the hand and mouth are even larger than in monkeys, whereas the area controlling the foot is much smaller. Penfield emphasized that this cartoon illustrated the relative size of the representation of each body part in the motor map; he did not claim that each body part was controlled by a single separate part of the motor map.

demonstrated that the same general topographic organization is conserved across many species. One important discovery was that the motor map is not a point-to-point representation of the body. Instead, the most finely controlled body parts, such as the fingers, face, and mouth, are represented in the motor map by disproportionately large areas, reflecting the larger number of neurons needed for fine motor control.

Woolsey and Penfield both recognized, however, that their simple motor map masked a deeper complexity. Today the best-studied regions of the map are those parts controlling the arm and hand. Recent mapping studies have revealed that the neurons controlling the muscles of the digits, hand, and distal arm tend to be concentrated within a central zone, whereas those controlling more proximal arm muscles are located in a horseshoe-shaped ring around the central core (Figure 37–2A). Furthermore, across the concentrically organized areas of the arm motor map there is

extensive overlap of stimulation sites that causes contractions of muscles acting across different joints; conversely, each muscle can be activated by stimulating many widely dispersed sites (Figure 37–2B). Moreover, different combinations of muscle contractions and joint motions can be evoked by stimulating different sites. Finally, local horizontal axonal connections link different sites, allowing neural activity at multiple output sites in the map to be coordinated during the formation of motor commands.

To date, studies have not revealed any repeating functional elements in the fine details of the motor map for the arm and hand analogous to the ocular-dominance bands and orientation pinwheels in the visual cortex. However, the complex, extensively overlapped organization of the arm motor map and the network of local horizontal connections likely provide a mechanism to coordinate whole-limb actions such as reaching to grasp and manipulate an object.

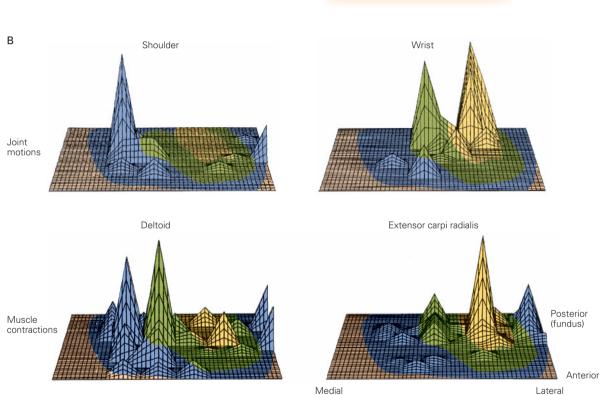

Figure 37–2 Internal organization of the motor map of the arm in the motor cortex.

A. The arm motor map in monkeys has a concentric, horse-shoe-shaped organization: Neurons that control the distal arm (digits and wrist) are concentrated in a central core (yellow) surrounded by neurons that control the proximal arm (elbow and shoulder; blue). The neuron populations that control the distal and proximal parts of the arm overlap extensively in a zone of proximal-distal cofacilitation (green). The arm motor representation is seen in its normal anatomical location in the anterior bank of the central sulcus (left), and also after flattening and rotation to bring it into approximate alignment with the microstimulation maps in part B. (Reproduced, with permission, from Park et al. 2001.)

B. Microstimulation of several sites in the arm motor map can produce rotations of the same joint. Neurons that control wrist movements are concentrated in the central core whereas those that regulate shoulder movements are distributed around the core, with some overlap between the two populations. In these maps, the height of each peak is scaled to the inverse of the stimulation current: the higher the peak, the lower the current necessary to produce a response. The distribution and overlap of stimulation sites that evoke contractions of muscles in the shoulder (deltoid) and wrist (extensor carpi radialis) are even more extensive than that of sites for joint rotations. The yellow, green, and blue color zones on these maps correspond only approximately to the functional zones identified in the motor map of part A. (Reproduced, with permission, from Humphrey and Tanji 1991.)

Many Cortical Areas Contribute to the Control of Voluntary Movements

Voluntary Motor Control Appears to Require Serial Processing

Much of what we do in everyday life involves a sequence of actions. One normally does not take a shower after getting dressed or put cake ingredients into the oven to bake before blending them into a batter. It seems logical that most brain functions are also serial.

Largely on the basis of indirect psychological studies, the neural processes by which the brain controls voluntary behavior are commonly divided into three sequential stages. First, perceptual mechanisms generate a unified sensory representation of the external world and the individual within it. Next, cognitive processes use this internal replica of the world to decide on a course of action. Finally, the selected motor plan is relayed to action systems for implementation (Figure 37–3A).

The final stage, execution of the chosen motor plan, also appears to be serial in nature. It has often been modeled as a series of sensorimotor transformations of representations of a movement into different coordinate frameworks, progressing from a general description of the overall form of the movement to increasingly specific details, culminating in patterns of muscle activity (Figure 37–3B).

According to this serial scheme, each sequential operation is encoded by a different neuronal population. Each population encodes specific features or parameters of the intended movement in a particular coordinate system, such as the direction of movement of the hand through space or the patterns of muscle contractions and forces. These several populations are connected serially and only the last population in the chain projects to the spinal cord.

As we shall see in this and the next chapter, this model has some heuristic value for describing how the brain is organized to control voluntary movement,

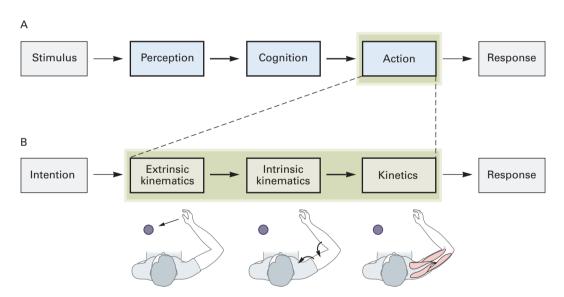

Figure 37–3 Cortical control of voluntary behavior appears to be organized in a hierarchical series of operations.

A. The brain's control of voluntary behavior has often been divided into three main operational stages, in which perception generates an internal neuronal image of the world, cognition analyzes and reflects on this image to decide what to do, and the final decision is relayed to action systems for execution. However, this three-stage serial organization was largely based on introspective psychological studies rather than on direct neurophysiological study of neural mechanisms.

B. Each of the three main operational stages is presumed to involve its own serial processes. For example, the "action" stage that converts an intention into a physical movement is

often presumed to involve a hierarchy of operations that transform a general plan into progressively more detailed instructions about its implementation. The model shown here, inspired by early controller designs for multijoint robots, suggests that the brain plans a chosen reaching movement by first calculating the extrinsic kinematics of the movement (eg, target location, trajectory of hand displacement from the starting location to the target location), then calculating the required intrinsic kinematics (eg, joint rotations) and finally the causal kinetics or dynamics of movement (eg, forces, torques, and muscle activity). (See also Figure 33–2.)

but direct neurophysiological studies of neural mechanisms show that a strict adherence to serial processing is simplistic and incorrect. We know now for instance that the brain does not have a single, unified perceptual representation of the world (see Chapter 38). The serial scheme also wrongly implies that the only role of the motor system is to determine which muscles to contract, when, and by how much. We now know that several cortical motor areas also play a critical role in the actual choice of what action to take, a process that is usually considered more "cognitive" than "motor." This is described in more detail in Chapter 38.

The Functional Anatomy of Precentral Motor Areas is Complex

In the early 20th century Alfred Campbell and Korbinian Brodmann divided the human cerebral cortex into a large number of cytoarchitectonic areas with distinct anatomical features. They noted that the *precentral cortex* in

the gyri immediately rostral to the central sulcus lacks the six layers characteristic of most cerebral cortex. It lacks a distinct internal granule cell layer and thus is often called *agranular cortex*. Campbell and Brodmann subdivided the precentral cortex into caudal and rostral parts, which Brodmann designated cytoarchitectonic areas 4 and 6 (Figure 37–4).

Campbell proposed that these two regions were functionally distinct motor areas. He thought that the caudal region, or *primary motor cortex*, controlled the motor apparatus in the spinal cord and generated simple movements. The rostral region, he argued, was specialized for higher-order aspects of motor control and for movements that are more complex, conditional, and voluntary in nature. He thought that these areas influenced movement indirectly by projecting to the primary motor cortex and so he named them the *premotor cortex*.

Some years later, while mapping motor areas of cortex with electrical stimuli, Clinton Woolsey and

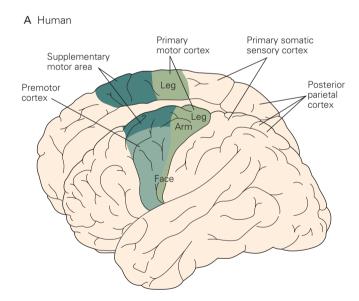

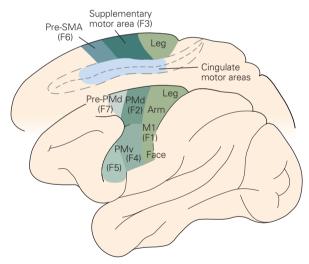

Figure 37–4 Multiple areas of the cerebral cortex are devoted to motor control and many are somatotopically organized.

A. Based on their histological studies at the beginning of the 20th century, Korbinian Brodmann and Alfred Campbell each divided the precentral cortex in humans into two anatomically distinct cytoarchitectonic areas: the primary motor cortex (Brodmann's area 4) and premotor cortex (Brodmann's area 6). Subsequent studies by Woolsey and colleagues led to subdivision of the premotor cortex into medial and lateral halves, the supplementary motor area and lateral premotor cortex, respectively. Since those pioneering studies the human premotor cortex and supplementary motor area have been subdivided into

B Macaque monkey

several smaller functional areas whose homologs can be seen in nonhuman primates. The medial surface of the hemisphere is shown in this and other similar figures as if reflected in a mirror.

B. More recent studies have subdivided the premotor cortex of macaque monkeys into several more functional zones with different patterns of cortical and subcortical anatomical connections and different neuronal responses during various motor tasks. A similarly detailed functional subdivision of the parietal cortex has also been made (not illustrated). (M1, primary motor cortex; Pre-SMA, pre-supplementary motor area; PMd, dorsal premotor cortex; Pre-PMd, pre-dorsal premotor cortex; PMv, ventral premotor cortex.)

his colleagues discovered that movements of the contralateral body can be evoked not only by electrical stimulation of the primary motor cortex, but also by stimulating a second region in a part of the premotor cortex on the medial surface of the cerebral hemisphere now known as the *supplementary motor area* (Figure 37–4B). The motor map of different body parts evoked by stimulation of the supplementary motor area is less detailed than that of the primary motor cortex and lacks the enlarged distal arm and hand representation seen in the primary motor cortex. Stimulation of the supplementary motor area can evoke movements on both sides of the body or halt ongoing voluntary movements, effects that rarely result from stimulation of the primary motor cortex.

Anatomical and functional studies in humans and nonhuman primates over the past 25 years have radically changed the view of how the precentral cortex is organized functionally. First, architectonic studies demonstrated that Brodmann's area 6 is not homogeneous but consists of several distinct subareas. Second, these subareas have specific connections among themselves and with the rest of the cerebral cortex. Third, functional studies found that each subarea separately controls movements of some or all parts of the body and that the properties of neurons in each subarea differ in important ways. These areas are identified by two different nomenclatures in the literature.

As a result, in current maps of the precentral cortex Brodmann's area 6 is usually divided into five or six functional areas in addition to the *primary motor cortex* (or area F1) in Brodmann's area 4 (Figure 37-4B). The classical supplementary motor area originally identified by Woolsey on the medial cortical surface is now split into two functional regions. The more caudal part is called the supplementary motor area proper (area F3), whereas the more rostral part is the pre-supplementary motor area (F6). The caudal and rostral parts of the dorsal convexity of area 6 are called the dorsal premotor cortex (F2) and predorsal premotor cortex (F7), respectively. The ventral convexity of Brodmann's area 6 has also been identified as a separate functional area called the *ventral premotor cortex*, and has been further subdivided into two subareas called F4 and F5 (Figure 37–4B). Finally, three additional motor areas outside Brodmann's area 6, in the rostral cingulate cortex, have been delineated recently.

The multiplicity of cortical motor areas would seem redundant if their only role was to initiate or coordinate muscle activity. However, we now know that neurons in these areas have unique properties and interact to perform diverse operations that select, plan, and generate actions appropriate to external and internal needs and context.

The Anatomical Connections of the Precentral Motor Areas Do Not Validate a Strictly Serial Organization

To understand the roles of these multiple precentral motor areas in voluntary motor control, it is important to know their connections with one another, their connections with other cortical areas, and their descending projections.

The cortical motor areas are interconnected by complex patterns of reciprocal, convergent, and divergent projections rather than simple serial pathways. The supplementary motor area, dorsal premotor cortex, and ventral premotor cortex have somatotopically organized reciprocal connections not only with the primary motor cortex but also with each other. The primary motor cortex and supplementary motor area receive somatotopically organized input from the primary somatosensory cortex and the rostral parietal cortex, whereas the dorsal and ventral premotor areas are reciprocally connected with progressively more caudal, medial, and lateral parts of the parietal cortex. These somatosensory and parietal inputs provide the primary motor cortex and caudal premotor regions with sensory information to organize and guide motor acts.

In contrast, the pre-supplementary and pre-dorsal premotor areas do not project to the primary motor cortex and are only weakly connected with the parietal lobe. They receive higher-order cognitive information through reciprocal connections with the prefrontal cortex and so may impose more arbitrary context-dependent control over voluntary behavior.

Several cortical motor regions project in multiple parallel tracts to subcortical areas of the brain as well as the spinal cord. The best studied output path is the *pyramidal tract*, which originates in cortical layer V in a number of precentral and parietal cortical areas. Precentral areas include not only primary motor cortex but also the supplementary motor and dorsal and ventral premotor areas. The pre-supplementary motor and pre-dorsal premotor areas do not send axons to the spinal cord; their descending output reaches the spinal cord indirectly through projections to other subcortical structures. Parietal areas that contribute descending axons to the pyramidal tract include the primary somatosensory cortex and adjacent rostral parts of the superior and inferior parietal lobules.

Many pyramidal tract axons decussate at the pyramid and project to the spinal cord itself, forming the *corticospinal tract* (Figure 37–5A). Because several cortical areas contribute axons to the corticospinal tract, the traditional view that the primary motor cortex is the "final common path" from the cerebral cortex to the

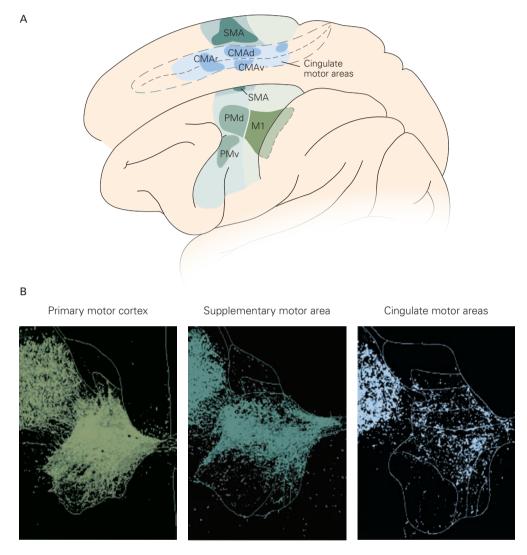

Figure 37–5 Cortical origins of the corticospinal tract. (Reproduced, with permission, from Dum and Strick 2002.)

A. Neurons that modulate muscle activity in the contralateral arm and hand originate in the primary motor cortex (M1) and many subdivisions of the premotor cortex (PMd, PMv, SMA) and project their axons into the spinal cord cervical enlargement. Corticospinal fibers projecting to the leg, trunk, and other somatotopic parts of the brain stem and spinal motor system originate in the other parts of the motor and premotor cortex. (M1, primary motor cortex; SMA, supplementary motor area; PMd, dorsal premotor cortex; PMv, ventral premotor cortex; CMAd, dorsal cingulate motor area; CMAv, ventral cingulate motor area; CMAr, rostral cingulate motor area.)

B. The axons of corticospinal fibers from the primary motor cortex, supplementary motor area, and cingulate motor areas terminate on interneuronal networks in the intermediate laminae (VI, VII, and VIII) of the spinal cord. Only the primary motor cortex contains neurons whose axons terminate directly on spinal motor neurons in the most ventral and lateral part of the spinal ventral horn. Rexed's laminae I to IX of the dorsal and ventral horns are shown in faint outline. The dense cluster of labeled axons adjacent to the dorsal horn (upper left) in each section are the corticospinal axons descending in the dorsolateral funiculus, before entering the spinal intermediate and ventral laminae.

spinal cord is incorrect. Instead, several premotor and parietal areas of cortex can also influence spinal motor function through their own corticospinal projections.

Many corticospinal axons from the primary motor cortex and premotor areas in primates, and virtually all corticospinal axons in other mammals, terminate on spinal interneurons in the intermediate region of the spinal cord (Figure 37–5B). These interneurons are components of reflex and pattern-generating circuits that produce stereotypical motor synergies and locomotor rhythms (see Chapter 36). In primates much of the control exerted by the primary motor cortex on spinal motor circuits and all of the control from premotor areas is mediated indirectly through these descending cortical projections to spinal interneurons.

In primates the terminals of some corticospinal axons also extend into the ventral horn of the spinal cord (lamina IX) where they arborize and contact the dendrites of spinal motor neurons (Figure 37–6B; Figure 37–5B). These monosynaptically projecting cortical neurons are called *corticomotoneurons*. The axons of these neurons become a progressively larger component of the corticospinal tract in primate phylogeny from prosimians to monkeys, great apes, and humans.

In monkeys corticomotoneurons are found only in the most caudal part of the primary motor cortex that lies within the anterior bank of the central sulcus. There is extensive overlap in the distribution of the corticomotoneurons that project to the spinal motor neuron pools innervating different muscles (Figure 37–6A). In monkeys more corticomotoneurons project to the motor neuron pools for muscles of the digits, hand, and wrist than to those for more proximal parts of the arm.

The terminal of a single corticomotoneuron axon often branches and terminates on spinal motor neurons for several different agonist muscles, and can also influence the contractile activity of still more muscles through synapses on spinal interneurons (Figure 37–6B, C). This termination pattern is functionally organized to produce coordinated patterns of activity in a *muscle field* of agonist and antagonist muscles. Most frequently, a single corticomotoneuron axon directly excites the spinal motor neurons for several agonist muscles and indirectly suppresses the activity of some antagonist muscles through local inhibitory interneurons (Figure 37–6C). The fact that corticomotoneurons are more prominent in humans than in monkeys may be one of the reasons why lesions of the primary motor cortex have such a devastating effect on motor control in humans compared to lower mammals (Box 37–1).

Although neurons in several motor-cortical areas send axons into the corticospinal tract, the primary

motor cortex has the most direct access to spinal motor neurons, including the monosynaptic projections of corticomotoneurons. However, the corticospinal tract is not the only pathway for descending control signals to spinal motor circuits. The spinal cord also receives inputs from the rubrospinal, reticulospinal, and vestibulospinal tracts. These pathways influence movement through monosynaptic terminations onto spinal interneurons and spinal motor neurons.

In summary, a strictly serial organization of voluntary movement would require a pattern of serial connections between cortical areas, ending at the primary motor cortex, which then projects to the spinal cord. In reality, however, the multiple precentral and parietal cortical motor areas are interconnected by a complex network of reciprocal, divergent, and convergent axonal projections. Moreover, several cortical areas project to the spinal cord in parallel with projections from the primary motor cortex. Finally, the spinal motor circuits receive inputs from several subcortical motor centers in addition to those from the cerebral cortex.

The Primary Motor Cortex Plays an Important Role in the Generation of Motor Commands

In the 1950s Herbert Jasper and colleagues pioneered chronic microelectrode recordings from alert animals engaged in natural behaviors. This approach, which allows researchers to study the activity of single neurons while animals perform a controlled behavioral task, has made enormous contributions to our knowledge of the neuronal mechanisms underlying many brain functions. A microelectrode can also be used to deliver weak electrical currents to a small volume of tissue around its tip. When used in the cerebral cortex, this technique is called *intracortical microstimulation*.

These methods have been complemented more recently by techniques that can be used in human subjects, such as functional imaging and transcranial magnetic stimulation. Nearly every insight that will be described in the rest of this chapter and in Chapter 38 has been derived from these techniques.

Edward Evarts, the first to use chronic microelectrode recordings to study the primary motor cortex in behaving monkeys, made several discoveries of fundamental importance. He found that single neurons in this area discharge during movements of a limited part of the contralateral body, such as one or two adjacent joints in the hand, arm, or leg (Figure 37–9). Some neurons discharge during flexion of a particular

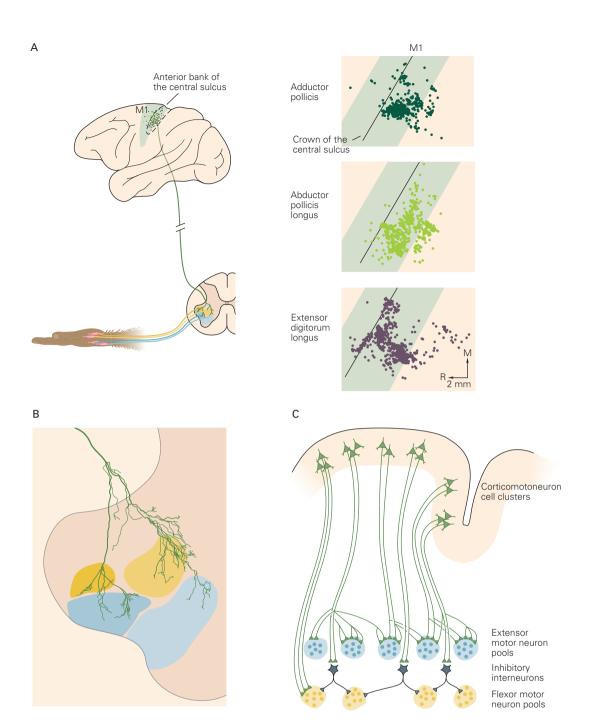

Figure 37–6 Corticomotoneurons activate complex muscle patterns through divergent connections with spinal motor neurons that innervate different arm muscles.

A. Corticomotoneurons, which project monosynaptically to spinal motor neurons, are located almost exclusively in the caudal part of the primary motor cortex (M1), within the anterior bank of the central sulcus. The corticomotoneurons that control a single hand muscle are widely distributed throughout the arm motor map, and there is extensive overlap of the distribution of neurons projecting to different hand muscles. The distributions of the cell bodies of corticomotoneurons that project to the spinal motor neuron pools that innervate the adductor pollicis, abductor pollicis longus, and extensor digitorum communis (shown on the right), illustrate this pattern. (R, rostral; M medial.) (Reproduced, with permission, from Rathelot and Strick 2006.)

B. A single corticomotoneuron axon terminal is shown arborized in the ventral horn of one segment of the spinal cord.

It forms synapses with the spinal motor neuron pools of four different intrinsic hand muscles (yellow and blue zones) as well as with surrounding interneuronal networks. Each axon has several such terminal arborizations distributed along several spinal segments. (Reproduced, with permission, from Shinoda, Yokata, and Futami 1981.)

C. Different colonies of corticomotoneurons in the primary motor cortex terminate on different combinations of spinal interneuron networks and spinal motor neuron pools, thus activating different combinations of agonist and antagonist muscles. Many other corticospinal axons terminate only on spinal interneurons (not shown). The figure shows corticomotoneuronal projections largely onto extensor motor neuron pools. Flexor motor pools receive similar complex projections (not shown). (Modified, with permission, from Cheney, Fetz, and Palmer 1985.)

Box 37–1 Lesion Studies of Voluntary Motor Control

Naturally occurring or experimentally induced lesions have long been used to infer the roles of different neural structures in motor control. However, the effects of lesions must always be interpreted with caution.

It is often incorrect to conclude that the function perturbed by an insult to a part of the motor system resides uniquely in the damaged structure, or that the injured neurons explicitly perform that function. Furthermore, the effects of lesions can be masked or altered by compensatory mechanisms in remaining, intact structures. Nevertheless, lesion experiments have been fundamental in differentiating the functional roles of cortical motor areas as well as the pyramidal tract.

Focal lesions of the primary motor cortex typically result in such symptoms as muscle weakness, slowing and imprecision of movements, and discoordination of multijoint motions, perhaps as a result of selective perturbations of the control circuitry for specific muscles (Figure 37–7). Larger lesions lead to temporary or permanent paralysis.

If the lesion is limited to a part of the motor map, the paralysis affects primarily the movements represented in that sector, such as the contralateral arm, leg, or face. There is diminished use of the affected body parts, and movements of the distal extremities are much more affected than those of the proximal arm and trunk

The severity of the deficit as a result of focal lesions also depends on the degree of required skill. Control of fine motor skills, such as independent movements of the fingers and hand and precision grip, is abolished. Any residual control of the fingers and the hand is usually reduced to clumsy, claw-like, synchronous flexion and extension motions of all fingers, not unlike the unskilled grasps of young infants. Even remaining motor functions, such as postural activity, locomotion, reaching, and grasping objects with the whole hand, are often clumsy and lack refinement.

Large lesions of the motor cortex or its descending pathways (for example the internal capsule) often produce a suite of symptoms known as the pyramidal syndrome (Figure 37–8). This condition is characterized by contralateral paralysis; increase of muscular tone (spasticity), often preceded by a transient phase of flaccid paralysis with decreased muscle tone; increase of deep reflexes (such as the patellar reflex); disappearance of superficial reflexes (such as the abdominal reflex); and appearance of the Babinski reflex (dorsiflexion of the great toe and fanning of the other toes when a blunt needle is drawn along the lateral edge of the sole). The increase in muscle tone alters the patient's posture, such

that the arm contralateral to the lesion is flexed and adducted whereas the leg is extended.

The term "pyramidal syndrome" is a misnomer. In fact, the symptoms result from lesions of descending cortical projections to several subcortical sites, not just the pyramidal tract. Spasticity, for instance, results from damage to nonpyramidal fibers, specifically those that innervate the brain stem centers involved in the control of muscular tone. Clear evidence for this comes from observation of the behavior of monkeys following surgical transection of the medullary pyramid, an anatomical structure that contains only pyramidal tract fibers. Transection at this level produces contralateral hypotonia rather than spasticity.

Lesions of the primary motor cortex in humans perturb the dexterous execution of movements, with deficits ranging from weakness and discoordination to complete paralysis. Lesions of other cortical regions, in contrast, do not result in paralysis and have less impact on the execution of movements than on the organization of action. One effect is difficulty in suppressing the natural motor response to a stimulus in favor of other actions that would be more appropriate to accomplish a goal.

For example, when a normal monkey sees a tasty food treat behind a small transparent barrier, it readily reaches around the barrier to grasp it. However, after a large premotor cortex lesion the monkey persistently tries to reach directly toward the treat rather than making a detour around the barrier, and thus repeatedly strikes the barrier with its hand.

Focal lesions of premotor areas cause a variety of more selective deficits that do not result from an inability to perform individual actions but rather an inability to choose the appropriate course of action. Lesions or inactivation of the ventral premotor cortex perturb the ability to use visual information about an object to shape the hand appropriately for the object's size, shape, and orientation before grasping it. Lesions of the dorsal premotor cortex or supplementary motor area impact the ability to learn and recall arbitrary sensorimotor mappings such as visuomotor rotations, conditional stimulus-response associations, and temporal sequences of movement.

The effects of motor cortex lesions also differ across species. Large lesions in cats do not cause paralysis; the animals can move and walk on a flat surface. However, they have severe difficulties using visual information to navigate within a complex environment, avoid obstacles, or climb the rungs of a ladder. Trevor Drew and col-

(continued)

Box 37-1 Lesion Studies of Voluntary Motor Control (continued)

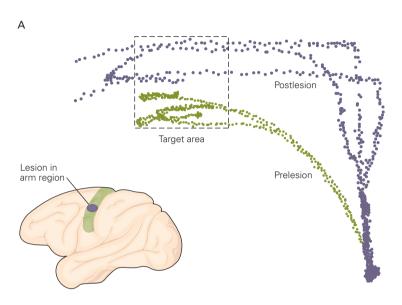

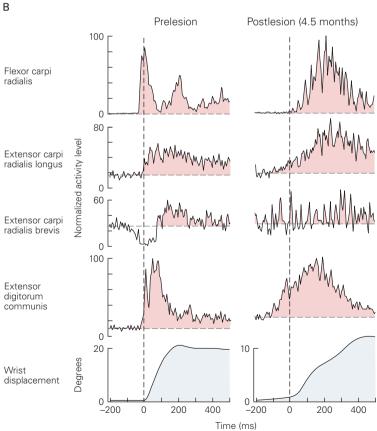

Figure 37–7 Fractionated control of muscle activity patterns requires cortical input.

A. A monkey can readily make diagonal movements of the wrist that require complex coordinated muscle patterns before a motor cortical lesion ("prelesion"). After a large lesion of the arm region of the motor cortex, the monkey shows major deficits in the ability to make diagonal movements even after lengthy rehabilitation.

B. The movement deficit is accompanied by a severe loss of the ability to make precisely timed fractionated muscle contractions of different agonist and antagonist muscles. (Reproduced, with permission, from Hoffman and Strick 1995.)

leagues have shown that pyramidal tract neurons in the motor cortex of cats are much more strongly activated when the cats must modify their normal stepping to clear an obstacle under visual guidance than during normal, unimpeded locomotion over a flat, featureless surface.

Similar lesions of motor cortex in monkeys have more drastic consequences, including initial paralysis and usually the permanent loss of independent, fractionated movements of the thumb and fingers. Monkeys nevertheless recover some ability to make clumsy movements of the hands and arms and to walk and climb, even after large lesions (Figure 37–8). In humans large lesions of the motor cortex are particularly devastating, often resulting in flaccid or spastic paralysis with a limited potential for recovery.

These differences in primates and man presumably reflect the increased importance in man of descending signals from motor cortex and a correspondingly diminished capacity of subcortical motor structures to compensate for the loss of those descending signals.

Figure 37–8 A lesion of the pyramidal tract abolishes fine grasping movements.

A. A monkey is normally able to make individuated movements of the wrist, fingers, and thumb in order to pick up food in a small well.

B. After bilateral sectioning of the pyramidal tract the monkey can remove the food only by grabbing it clumsily with the whole hand. This change results mainly from the loss of direct inputs from corticomotoneurons onto spinal motor neurons. A pyramidal tract transection is not equivalent to a motor cortex lesion, however, because not all pyramidal tract axons terminate in the spinal cord. The axons that do project to the spinal cord originate in several cortical areas, including the motor cortex, and the corticospinal tract is only one of several parallel output pathways of the motor cortex. (Reproduced, with permission, from Lawrence and Kuypers 1968.)

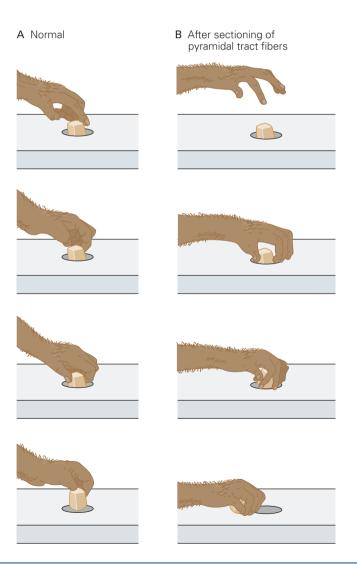

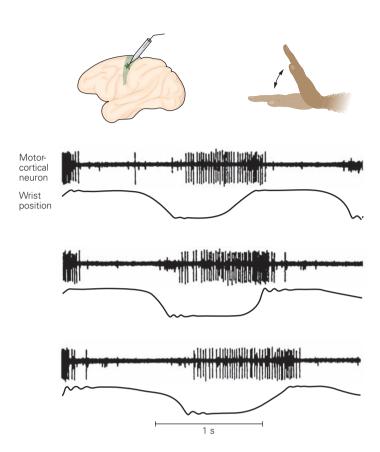

Figure 37-9 The discharge of individual pyramidal tract neurons varies with particular movements of specific parts of the body. The discharge of a motor cortex neuron with an axon that projects down the pyramidal tract is recorded while a monkey makes a sequence of flexion and extension movements of the wrist. The three parts of the figure show three consecutive flexion-extension cycles, proceeding from top to bottom. In the trace showing wrist position the direction of flexion is down and extension up. The pyramidal tract neuron discharges before and during extensions and is reciprocally silent during flexion movements. It does not discharge during movements of other body parts. Other motor cortex neurons show the opposite pattern of activity, discharging before and during flexion movements. (Reproduced, with permission, from Evarts 1968.)

joint and are reciprocally suppressed during extension, whereas other cells display the opposite pattern. This movement-related activity typically begins 50 to 150 ms before the onset of agonist muscle activity. These pioneering studies suggested that single neurons in primary motor cortex generate signals that provide specific information about movements of specific parts of the body before those movements are executed.

Many subsequent studies have provided further insight into the contribution of different cortical motor areas to the control of voluntary movements. In general, the output signals from premotor areas are strongly dependent on the context in which the action is performed, such as the stimulus-response associations and the rules that guide which movement to make. In contrast, the commands generated by the primary motor cortex are more closely related to the mechanical details of the movement and are usually less influenced by the behavioral context. However, the relative role of these different areas to voluntary motor control, including the primary motor cortex itself, continues to be an area of active research and controversy. The rest of this chapter and Chapter 38 describe our current understanding of the different roles of cortical motor areas.

Columnar arrays of neurons with similar response properties are a prominent feature of many sensory areas of cortex. It is surprising therefore that there is only weak evidence for such functional columns in the primary motor cortex. The cell bodies and apical dendrites of primary motor cortex neurons tend to form radially oriented columns. The terminal arbors of thalamocortical and corticocortical axons form localized columns or bands and corticomotoneurons tend to cluster in small groups with similar muscle fields. Motor cortex neurons recorded successively as a microelectrode descends perpendicularly through the neuronal layers between the pial surface and the white matter typically discharge during movements of the same part of body and can have similar preferred movement directions. Nevertheless, adjacent cells often show very different response patterns.

Motor Commands Are Population Codes

The complex overlapping organization of the motor map for the arm and hand suggests at least two different ways to generate the motor command for a given movement. The map could function as a *look-up table*

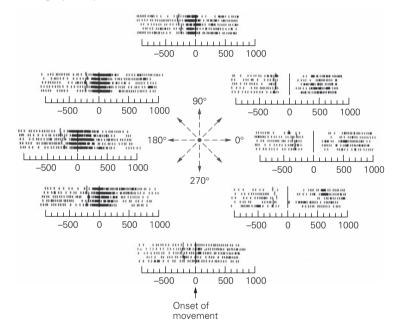

within which a desired movement is generated by selective activation of a few sites whose combined output produces all the required muscle activity and joint motions. Or it could be a distributed *functional map* in which many sites contribute to each motor command.

Apostolos Georgopoulos and colleagues recorded from the primary motor cortex while a monkey reached in different directions from a central starting position toward targets arrayed on a circle in the horizontal plane. Individual neurons responded during many movements, not just a single one (Figure 37–10A). Each

neuron's activity was strongest for a *preferred* direction and often weakest for the opposite direction, as Evarts had found for single-joint movements. However, each cell also responded in a graded fashion to directions of movement between the preferred and the opposite directions. Its activity pattern thus formed a broad directional tuning curve, maximal at the preferred direction and decreasing gradually with increasing difference between the preferred direction and the target direction.

Different cells had different preferred directions, and their tuning curves overlapped extensively.

A Single primary motor cortex neuron

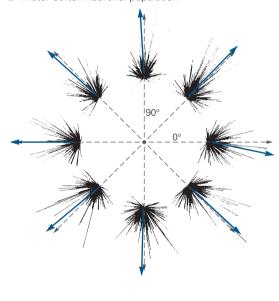

Figure 37–10 A reaching movement is coded by a population of neurons in the arm motor map.

A. Raster plots show the firing pattern of a single primary motor cortex neuron during movements in eight directions. The neuron discharges at the maximal rate for movements near 135 degrees and 180 degrees and at lesser intensities for movements in other directions. The cell's lowest firing rate is for movements opposite the cell's preferred direction. Different cells have different preferred directions, and their broad directional tuning curves overlap extensively. The plots are from a study in which a monkey was trained to move a handle to eight targets arranged radially on a horizontal plane around a central starting position. Each row of tics in each raster plot represents the activity in a single trial, aligned at the time of movement onset (time zero). (Reproduced, with permission, from Georgopoulos et al. 1982.)

B. Many primary motor cortex neurons with a broad range of preferred movement directions respond at different intensities during reaching movements in a particular direction. The overall

directional bias of the activity within the population of neurons shifts systematically with movement direction so that the vectorial sum of the activity of all cells is a population vector that closely matches that of the direction of movement. This shows that the motor command for a movement is generated by a widely distributed population of cells throughout the arm motor map, each of which fires at a different intensity for movement in a particular direction.

The eight single-neuron vector clusters and the population vectors shown here represent the activity of the same population of cells during reaching movements in eight different directions. The activity of each neuron during each reaching movement is represented by a thin black vector that points in the neuron's preferred movement direction and whose length is proportional to the discharge of the neuron during that movement. Blue arrows are the population vectors, calculated by vectorial addition of all the single-cell vectors in each cluster; dashed arrows represent the direction of movement of the arm. (Reproduced, with permission, from Georgopoulos et al. 1983.)

All directions were represented in the neuronal population. Cells with similar preferred directions were located at several different sites in the arm motor map, and nearby cells often had different preferred directions. As a result, many cells with a broad range of preferred directions discharged at different intensities at many locations across the arm motor map during each reaching movement.

Despite the apparent complexity of the response properties of single neurons, Georgopoulos found that the global pattern of activity of the entire population provided a clear signal for each movement. He represented each cell's activity by a vector pointing in the cell's preferred direction. The vector's length for each direction of movement was proportional to the mean level of activity of that cell averaged over the duration of the movement (Figure 37–10B). This vectorial representation implied that an increase of activity of a given cell is a signal that the arm should move in the cell's preferred direction, and that the strength of this directional influence varies continuously for different reach directions as a function of the neuron's directional tuning.

Vectorial addition of all of the single-cell contributions to each output command produces a *population vector* that corresponds closely to the actual movement direction. That is, an unambiguous signal about the desired motor output is encoded by the summed activity of a large population of active neurons throughout the arm motor map in the primary motor cortex. As a result, neurons in all parts of the arm motor map contribute to the motor command for each reaching movement, and the pattern of activity across the motor map changes continuously as a function of the intended direction of the reaching movement.

Andrew Schwartz and colleagues used the same population-vector analysis to represent temporal variations in the activity of populations of primary motor cortex neurons every 25 ms while monkeys performed continuous arm movements. In the resulting time sequence of population vectors, each vector predicts the instantaneous direction and speed of the motion of the monkey's arm approximately 100 ms later (Figure 37–11). These results show that the pattern of neural activity distributed across the arm motor map varies continuously in time during complex arm movements, signaling the moment-to-moment details of the desired movement.

Further studies have confirmed that similar population-coding mechanisms are used in all cortical motor areas. This common coding mechanism undoubtedly facilitates the communication of movement-related information between the multiple areas of motor cortex during voluntary behavior.

The Motor Cortex Encodes Both the Kinematics and Kinetics of Movement

Population-vector analyses show that neural activity in the primary motor cortex contains information about the trajectory of hand motions during reaching and drawing movements. However, to execute those movements the motor system must implement the desired motions by generating particular patterns of muscle activity.

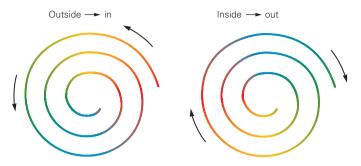

Electrical stimulation of the primary motor cortex readily evokes muscle contractions, and some cells in this region have direct access to spinal motor neurons. Indeed, it was long assumed that the major role of the primary motor cortex was to specify the muscle activity that generates voluntary movements. Because muscle contractions generate the forces that displace a joint or limb in a particular direction, a critical question is whether primary motor cortex neurons signal the desired spatiotemporal form of a behavior or the forces and muscle activity required to generate the movement. That is, do these neurons encode the kinematics or the kinetics of an intended movement (Box 37–2)?

Kinematics refers to the parameters that describe the spatiotemporal form of movement, such as direction, amplitude, speed, and path. Kinetics concerns the causal forces and muscle activity. It is also useful to distinguish the *dynamic* forces that cause movements from the *static* forces required to maintain a given posture against constant external forces such as gravity.

Evarts was the first to address this question with single-neuron recordings. Using a system of pulleys and weights, he applied a load to the wrist of a monkey to pull the wrist in the direction of flexion or extension. To make a particular movement the animal had to alter its level of muscle activity to compensate for the load. As a result, the kinematics (direction and amplitude) of wrist movements remained constant but the kinetics (forces and muscle activity) changed with the load. The activity of many primary motor cortex neurons associated with movements of the hand and wrist increased during movements in their preferred direction when the load opposed that movement but decreased when the load assisted it (Figure 37-12). These changes in neural activity paralleled the changes in muscle activity required to compensate for the external loads. This was the first study to show that the activity of many primary motor cortex neurons is more closely related to how a movement is performed, the kinetics of motion, than to what movement is performed, the corresponding kinematics.

A later study confirmed this property of motor cortex activity during whole-arm reaching movements.

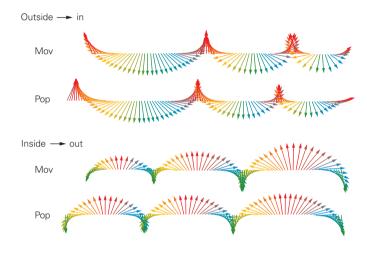

B Temporal sequence of movement vectors

Figure 37–11 The moment-to-moment activity of a population of motor cortex neurons predicts arm movements over time. (Reproduced, with permission, from Moran and Schwartz 1999.)

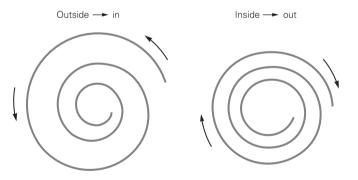

A. A monkey uses its arm to trace spirals with its finger.

B. Temporal sequences of vectors, reading left to right, illustrate the instantaneous direction and speed of movement of the finger (Mov) and the net population vector signal (Pop) of the activity of 241 motor cortex neurons every 25 ms during the drawing movements. The population vectors precede the hand displacement vectors by approximately 100 ms.

C. Joining the instantaneous population vectors tip to tail produces "neural trajectories" that predict the spatial trajectory of movement of the finger along the spiral path approximately 100 ms in the future.

C Predicted trajectories made by joining instantaneous population vectors from part B tip to tail

A monkey made arm movements exactly as in the task used by Georgopoulos (Figure 37–10), but additional external loads pulled the arm in different directions. To continue to move the arm along the same path, the monkey had to change the activity of its arm muscles to counteract the external loads. The level of activity

of many motor cortex neurons changed systematically with the direction of the external load even though the movement path did not change. When the load opposed the direction of reach, the single-cell and total population activity increased. When the load assisted the reaching direction, the neural activity decreased

Box 37–2 The Equilibrium-Point Hypothesis of Movement

Most theoretical and neurophysiological studies of neural control of movement are based on variants of the force-control hypothesis, which states that the motor system controls a movement by planning and controlling its causal dynamic forces or muscle activity.

The position-control or equilibrium-point hypothesis, however, argues that cortical motor centers do not compute inverse kinematics or dynamics to specify the necessary muscle activity. Instead, this model proposes that the output from the motor cortex signals the desired spatial endpoints and equilibrium configurations of the arm and body, that is, the posture in which all external and internal (muscular) forces are at balance and no further movement occurs.

According to the equilibrium-point hypothesis, the motor cortex causes a movement of part or all of the body by generating a signal specifying a particular equilibrium or *referent configuration*. This descending signal

exploits spinal reflex circuits and the spring-like biomechanical properties of muscles to change muscle activity and create an imbalance between external and internal forces, causing the limb to move until equilibrium is restored

If no external force is applied to the limb, the desired, signaled, and actual equilibrium configurations should all correspond. If the motor system is confronted with an external force, however, it must signal a different referent configuration whose internal forces compensate for the external forces. Thus, according to the equilibrium-point hypothesis, the motor cortex commands the desired movement without computing the complex transformations required to encode the required forces and muscle activities. According to the hypothesis, the inverse-kinematics and inverse-dynamics transformations occur implicitly at the local spinal cord circuits and in the motor periphery itself.

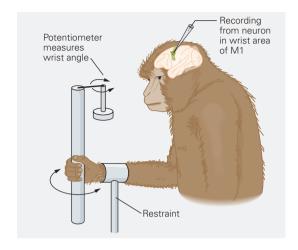

in a manner that signaled the change in muscle activity and output forces required to make the movement (Figure 37–13).

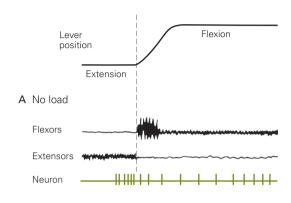

Other studies have examined the issue whether the primary motor cortex organizes the kinematics or kinetics of movement by using tasks in which subjects generate isometric forces against immovable objects rather than moving the arm. The activity of many primary motor cortex neurons varies with the direction and level of static isometric output forces generated across a single joint, such as the wrist or elbow, as well as during precise pinches with the thumb and index finger (Figure 37–14A). At least over part of the tested range these responses vary linearly with the level of static force. When a monkey uses its whole arm to exert isometric force in different directions, the activity of many motor cortex neurons varies systematically with force direction, and the directional tuning curves resemble those for activity associated with reaching movements (Figure 37–14B). Because no movement is intended or produced in isometric tasks, this strongly suggests that the primary motor cortex contributes to the control of static and dynamic output forces during many motor actions.

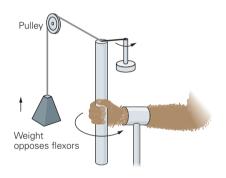

Finally, several studies have found that the activity of some motor cortex neurons can be correlated with the detailed contraction patterns of specific muscles during such diverse tasks as isometric force generation, precision pinching of objects between the thumb and index finger, and complex reaching and grasping actions (Figure 37–15).

These findings show that some neurons in the primary motor cortex can provide information about the causal forces and muscle activity of motor outputs. Nevertheless, the activity of other neurons in the primary motor cortex appears to signal the desired kinematics of arm and hand movements rather than their kinetics, or the desired direction of isometric force but not its magnitude. Perhaps most surprisingly, the activity of some corticomotoneurons does not always correlate with the contraction of their target muscles. For instance, some corticomotoneurons discharge strongly while a monkey generates weak contractions of the target muscles to make carefully controlled delicate movements of the hand and fingers, but are nearly silent when the monkey generates powerful contractions of the same muscles to make brisk, forceful movements.

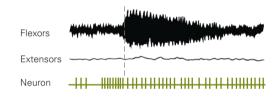

How can we reconcile these apparently contradictory findings about the role of the primary motor cortex in the control of movement? According to the serial model of motor control all of the neurons in the primary motor cortex should have similar properties and so should represent either the kinematics or kinetics of the desired movement, but not both.

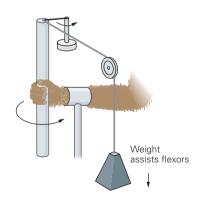

C Load assists flexors

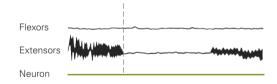

Figure 37–12 Activity of a motor cortex neuron correlates with changes in the direction and amplitude of muscle forces during wrist movements. The records are from a primary motor cortex (M1) neuron with an axon that projected down the pyramidal tract. The monkey flexes its wrist under three load conditions. When no load is applied to the wrist, the neuron fires before and during flexion (A). When a load opposing flexion is applied, the activity of the flexor muscles and the

neuron increases (B). When a load assisting wrist flexion is applied, the flexor muscles and neuron fall silent (C). In all three conditions the wrist displacement is the same, but the neuronal activity changes as the loads and compensatory muscle activity change. Thus the activity of this motor cortex neuron is better related to the direction and level of forces and muscle activity exerted during the movement than to the direction of wrist displacement. (Reproduced, with permission, from Evarts 1968.)

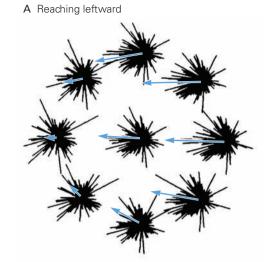

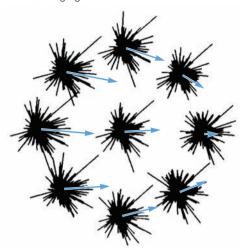

Figure 37–13 Activity of primary motor cortex neurons varies with the forces required to maintain the direction of reaching movements against external loads. A vectorial representation of the directional activity of approximately 260 motor cortex neurons (black lines) when a monkey makes reaching movements to the left and right. The vectors in the center represent activity when no external load is applied to the arm, whereas the vector clusters around the center represent the activity of the same 260 neurons when an external load pulls the arm in different directions. The location of each vector

B Reaching rightward

cluster relative to the central cluster corresponds to the direction in which the external load pulls on the arm. The change in population vectors (**blue arrows**) for the vector clusters around the center indicates that the strength and overall directional bias of the activity of the neural population vary systematically with the direction of the external load, in order to counteract its effect, even though the trajectory of the movement does not change. (Reproduced, with permission, from Kalaska et al. 1989.)

However, the experimental evidence suggests that a strictly serial model is too simplistic. The response properties of primary motor cortex neurons are not homogeneous. Signals about both the desired kinematics and required kinetics of movements may be generated simultaneously in different, or possibly even overlapping, populations of primary motor cortex neurons. Rather than representing only what movement to make (kinematics) or how to make it (kinetics), the true role of the motor cortex may be to perform the transformation between these two representations of voluntary movements.

Delineating the movement-related information encoded in motor cortex activity is increasingly important for the development of brain-controlled interfaces and neuroprosthetic controllers that allow patients with severe motor deficits to control remote devices such as a computer cursor, a wheelchair, or a robotic limb by neural activity alone (Box 37–3).

Hand and Finger Movements Are Directly Controlled by the Motor Cortex

The monosynaptic projection from the primary motor cortex onto spinal motor neurons is most dense for muscles of the distal arm, hand, and fingers. This arrangement allows the primary motor cortex to regulate the activity of those muscles directly, in contrast to its indirect regulation of muscles through the reflex and pattern-generating functions of the spinal circuits. It also provides primates and humans with a greatly enhanced capacity for individuated control of hand and finger movements. Large lesions of the primary motor cortex permanently destroy this capacity.

Although monkeys and humans can make isolated movements of the thumb and fingers, most hand and finger actions involve combinations of stereotypical hand and finger configurations and coordinated wrist and digit movements. This has led to the hypothesis that separate cortical circuits selectively control these different stereotypical hand actions, and that the primary motor cortex converts these signals into more specific motor commands (see Chapter 38).

The anatomy of the muscles of the wrist and fingers further complicates the commands for individuated finger and hand movements. Several muscles have long, bifurcating tendons that act across several joints and even act on several fingers rather than just one. As a consequence, individuated control of hand

and finger movements requires highly specific patterns of activation and inhibition of multiple muscles.

Cortical neurons controlling the hand and digits occupy the large central core of the primary motor cortex motor map but also overlap extensively with populations of neurons controlling more proximal parts of the arm (see Figure 37–2A). Some neurons within the central core discharge preferentially during movements of a single digit, but many discharge during coordinated movements of several digits, and even of the wrist and more proximal joints. Neurons that discharge during movements of different digits

are distributed throughout the motor map in an extensively overlapping fashion. As a result, neural activity required to generate an individuated action of the hand and digits is distributed broadly across the distal arm and hand areas of the motor map, as is also the case for the output to more proximal parts of the arm.

This highly intermixed organization of the hand and digit motor map stands in striking contrast to the much more highly ordered representation of tactile sensory inputs from different parts of the hand and digits in the primary somatosensory cortex. This difference likely reflects differences in the cortical mechanisms

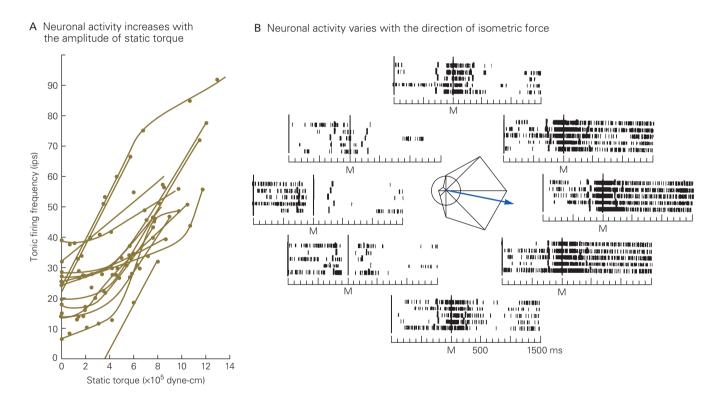

Figure 37–14 The firing rates of many primary motor cortex neurons correlate with the level and direction of force exerted in an isometric task.

A. The activity of many primary motor cortex neurons increases with the amplitude of static torque generated across a single joint. The plot shows the tonic firing rates of several different corticomotoneurons at different levels of static torque exerted in the direction of wrist extension. Other motor cortex neurons show increasing activity with torque exerted in the direction of wrist flexion, and so would show response functions with the opposite slope (not shown). (Reproduced, with permission, from Fetz and Cheney 1980.)

B. When a monkey uses its whole arm to push on an immovable handle in its hand, the activity of some primary motor cortex neurons varies with the direction of isometric forces. Each of the eight raster plots shows the activity of the same

primary motor cortex neuron during five repeated force ramps in one direction. Each row shows the pattern of spikes during a single trial of the task. The position of each raster of activity corresponds to the direction in which the monkey is generating isometric forces on the handle. The onset of the force ramp is indicated by the vertical line labeled **M**. The thick ticks to the left of that line in each row indicate when the target appeared on a computer monitor, telling the monkey the direction in which it should push on the handle. The central polar plot illustrates the directional tuning function of the neuron as a function of the direction of isometric forces. Note the similarity of the shapes of the tuning function for the direction of whole-arm isometric forces here and for whole-arm reaching movements in Figure 37–10A. (Reproduced, with permission, from Sergio and Kalaska 2003.)

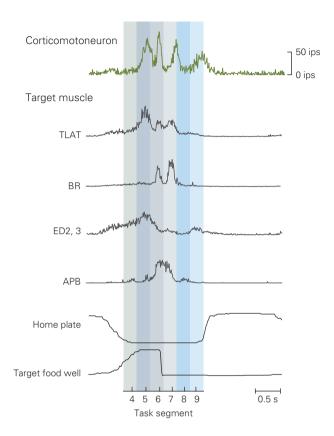

Figure 37–15 The activity of some primary motor cortex neurons can be correlated with particular patterns of muscle activity. The bursts of activity in a single corticomotoneuron during a reach-and-grasp movement to retrieve food pellets from a small well are correlated with bursts of contractile activity in several of its target muscles at different times during the movement. (APB, abductor pollicis brevis; BR, brachioradialis; ED2, 3, extensor digitorum 2, 3; TLAT, lateral triceps.) (Reproduced, with permission, from Griffin et al. 2008.)

required to analyze the spatiotemporal distribution of tactile input on the hand and digits versus those needed to coordinate individuated movements of the digits and hand.

Sensory Inputs from Somatic Mechanoreceptors Have Feedback, Feed-Forward, and Adaptive Learning Roles

Many primary motor cortex neurons receive sensory input from proprioceptors or cutaneous mechanoreceptors. The tactile input is particularly prominent on neurons implicated in the control of hand and digit movements. These inputs inform the motor system about the current state of the body, such as the position, posture, and movement of the arm and

hand and their interactions with the environment. This information can play at least three functional roles: in feedback control of ongoing movements, in feed-forward control of intended movements, and as a teaching signal during motor learning.

Sensory feedback from the arm provides information about both the progress of an ongoing arm movement and deviations from the intended path that should be corrected. Feedback corrections during movement are implemented by neural circuits at many levels of the motor system, ranging from reflex responses in the spinal cord to corrective adjustments of voluntary motor commands from the motor cortex. Similarly, the activity of many neurons in the primary motor cortex that control hand movements is strongly influenced by tactile stimuli on the glabrous surface of the digits and palm of the hand. This tactile input helps adjust the output signal from hand-related neurons to ensure that the subject applies enough force to the surface of an object to grasp and manipulate it, but not to crush it or let it slip.

Sensory feed-forward control involves continuously adjusting the level and distribution of neuronal activity throughout the cortical motor map to reflect the limb's current state of posture and movement. By pretuning the pattern of activity in the motor-cortical map and spinal motor apparatus as a function of the limb's motor state before the onset of a movement, somatic sensory input helps to assure that the appropriate motor command is generated in the motor cortex and converted into the appropriate patterns of muscle activity at the spinal level.

Finally, sensory input can provide information about errors experienced during movement that could be used by adaptive motor circuits to make changes to future motor commands, thus facilitating motor learning.

The Motor Map Is Dynamic and Adaptable

The mediolateral sequence of major body segments in the motor map is highly consistent across individuals, but the details in each functional subregion can vary. This suggests that the motor map is continually shaped by an individual's motor experience. The dynamic nature of the map has been demonstrated in several ways. For instance, functional reorganization often occurs after a focal lesion so that some of the movements that had been evoked by the injured tissue are now generated by the adjacent cortex. This reorganization likely contributes to the recovery of function after local infarcts.

Learning a motor skill can also induce reorganization. Randy Nudo and colleagues trained monkeys to

Box 37–3 Enhancing the Quality of Life of Neurological Patients: Brain-Machine Interfaces

Every year thousands of people suffer severe spinal cord trauma, subcortical strokes, or degenerative neuromuscular diseases such as multiple sclerosis and amyotrophic lateral sclerosis. Although their cortical motor systems remain largely intact and they try strenuously to move, they cannot convert their willful intentions into physical action.

These patients must depend on caregivers to attend to even their most basic needs. One of the greatest quality-of-life issues for these patients is the loss of autonomy resulting from the inability to move and sometimes even to communicate. Several technological solutions have been sought to enhance the autonomy of such patients.

One approach has been to use electroencephalographic activity recorded by scalp electrodes as a control signal for remote devices such as computer cursors or robotic tools. An alternative approach has been to record the eye movements of subjects and to use them as the control signals.

However, both methods have significant limitations. Electroencephalographic control often takes months to master because the subjects must learn how to synchronize the activity of large populations of neurons within a cortical region to generate an electrical signal that is recordable and discriminable in real time and without extensive averaging of multiple repetitions.

Eye-movement methods are much easier to implement and learn, but they prevent subjects from looking toward other objects of interest while attempting to perform a task. Moreover, both approaches require intense concentration and the focused attention of the subjects to the virtual exclusion of all other activities.

A major recent advance has been the development of brain-machine interfaces (also often called brain-computer, brain-controlled, or neuroprosthetic interfaces). This technology records neural activity reflecting the motor intentions of the individual and converts this activity into control signals for external devices. It exploits the discovery that information about static arm postures and the direction and velocity of arm movements can be extracted from the activity patterns of neuronal populations in the primary motor cortex and other arm movement-related areas of the cerebral cortex.

Brain-machine interfaces include four basic components:

 Implantable electrode arrays and associated hardware to record the activity of neuronal populations in a cortical area.

- 2. Computer algorithms to extract signals about the motor intentions of the individual.
- Interfaces to convert the extracted signals into control signals to generate the desired action by an external effector.
- 4. Sensory feedback signals to improve performance.

Originally tested in experimental animals, brainmachine interfaces are now undergoing clinical trials in human neurological patients. Severely paralyzed patients with multi-electrode arrays in the primary motor cortex are quickly able to learn to control a cursor on a computer monitor so as to operate computer programs, compose messages, track the random motions of a moving target, and control a simple robotic arm. The subjects are able to control the remote effectors merely by thinking about making the corresponding movements.

The centrally generated intentions activate motor cortex neurons in a manner similar to that during normal movements. The subjects can control the devices while at the same time engaged in other activities such as looking around the laboratory or even engaging in conversations. This ability dramatically illustrates the fact that much of the cortical activity that converts a motor intention into overt action occurs in the subconscious.

The initial studies using this technology demonstrated that electrodes implanted in different cortical areas yield different types of neural signals. Electrodes in the primary motor cortex provide the best signals for continuous control of the time-varying details of the kinematics and kinetics of the trajectory of a robotic device. Such control is particularly useful for tasks like manipulating objects and for making complex movements as in drawing or writing.

In contrast, signals from the premotor cortex and posterior parietal cortex may be more appropriate for specifying the overall goals and desired outcome of an action, such as the final target location, without elaborating the details of how to accomplish the goal.

A brain-controlled interface that uses a combination of signals from different cortical areas might afford a level of context-dependent control that resembles the normal voluntary control of behavior.

use precise movements of the thumb, index finger, and wrist to extract treats from a small well. After a monkey had become adept at the task, the area of its motor map in which intracortical microstimulation could evoke the skilled movements was larger than before training (Figure 37–16). If the monkey did not practice the task for a lengthy period, its skill level decreased, as did the cortical area from which the relevant movements could be elicited. Similar modifications of the representation of practiced actions have also been demonstrated in human motor cortex by functional imaging and transcranial magnetic stimulation.

John Donoghue and colleagues demonstrated that these adaptive changes depend on horizontal connections and local inhibitory circuits. They found two adjacent sites in the rat's motor map at which intracortical microstimulation caused contractions of muscles in the upper lips or forearm (Figure 37–17A). Within minutes after transection of the facial nerve innervating the lip muscles, stimulation of the lip-muscle site began to evoke contractions of forearm muscles.

In a related experiment they injected bicuculline into a forearm-muscle site in the motor cortex of an intact rat without a facial nerve transection to block the neurotransmitter GABA (γ -aminobutyric acid). Within minutes stimulation of the lip-muscle site evoked contractions of both lip and forearm muscles. They concluded that stimulation of the lip-muscle site activated local horizontal axons that projected into the forearm-muscle site, activity that was normally suppressed by GABAergic inhibitory interneurons (Figure 37–17B).

The Motor Cortex Contributes to Motor Skill Learning

One of the most remarkable properties of the brain is the adaptability of its circuitry to changes in the environment—the capacity to learn from experience and store the acquired knowledge as memories. When human subjects practice a motor skill their performance improves. Important advances have been made in understanding the mechanisms underlying the learning of motor skills, also known as procedural learning (see Chapter 66). For instance, Donoghue and colleagues found an increase in the synaptic strength of local horizontal connections between different parts of the arm motor map in rats that became increasingly skilled at reaching through a small hole in a transparent barrier to grasp, retrieve, and eat small food pellets.

Adaptation to perturbations of movement caused by external forces has been studied extensively in human subjects. One type of force field pushes on the arm in a direction perpendicular to the direction of the arm's movement; the strength of this force increases with movement speed. Although such *viscous curl* fields may seem odd, they are exactly the kind of forces that act on an arm when a person reaches out while simultaneously turning his or her body. Normally, these coriolis forces do not deflect the arm movement from its intended path because your motor system has learned to predict that these forces will arise during this natural behavior and generates a motor command that corrects for them in advance.

However, when a subject is stationary and unexpectedly encounters an experimentally generated viscous curl field for the first time during an arm movement, the arm is deflected sideways from its usual, nearly straight path and the hand path becomes curved. When the subject makes repeated movements in the same field, the movement paths become incrementally straighter until they are indistinguishable from movements without the curl field. If the force field is then unexpectedly turned off, the path of movement curves strongly in the opposite direction (Figure 37–18A). This *after-effect* demonstrates that the subject has changed the motor command required to produce the desired straight movement in anticipation of the perturbing effect of the force field.

As a subject adapts to the force field, motor behavior changes from feedback correction for actual perturbations to predictive feed-forward compensation for expected perturbation. Motor-learning theory suggests that this adaptive process may involve at least two distinct learning mechanisms, known as feedbackerror learning and supervised learning.

In feedback-error learning sensory signals about the experienced error both guide the correction for the immediate perturbation and alter adaptive feedback control circuits to permit more efficient compensation for expected perturbation. In supervised learning the motor system gradually adapts internal models, neural circuits that learn the relationship between desired movements and required motor commands in that environment (see Chapter 33). An internal forward model estimates the state of the limb in the near future based on an efference copy of the motor command and sensory feedback of the ongoing movement, and uses this estimate to generate an error signal proportional to the deviation of the estimated movement from its desired kinematics. An internal inverse model uses this and other error signals to learn how to generate the motor command that will produce a desired movement by compensating in a predictive manner for the anticipated perturbation. Neural circuits that constitute these internal forward and inverse models are thought

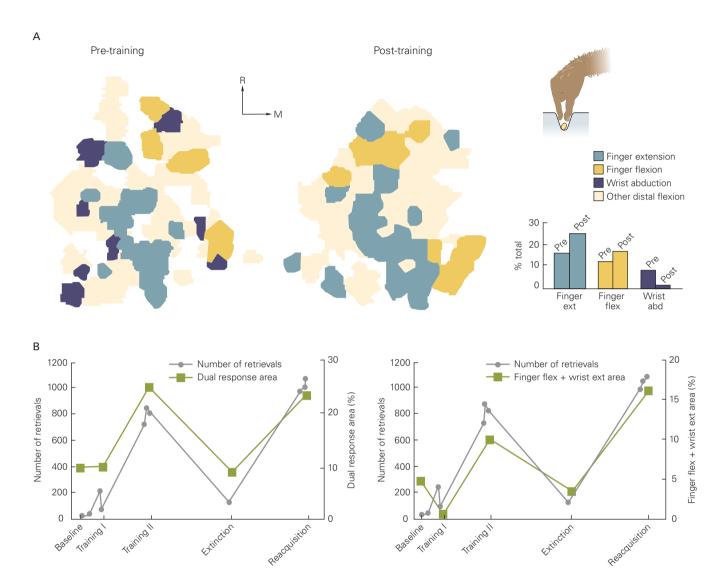

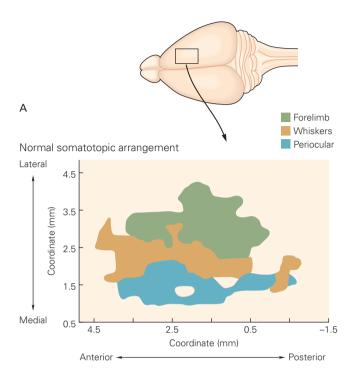

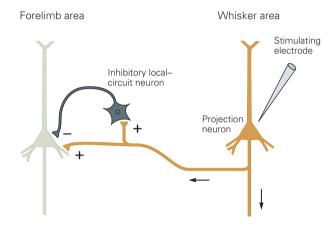

Figure 37–16 Learning a motor skill changes the organization of the motor map. (Reproduced, with permission, from Nudo et al. 1996.)

A. Motor maps for the hand in a monkey before and after training on retrieval of treats from a small well. Before training output sites that generate index finger and wrist movements occupy less than half of a monkey's motor map. After training the area from which those trained movements can be evoked by intracortical microstimulation expands substantially. The area of the map from which one could elicit individuated movements such as finger extension and flexion has expanded considerably, while the areas controlling wrist abduction, which this monkey used less in the new skill, became less prominent. (R, rostral; M, medial.)

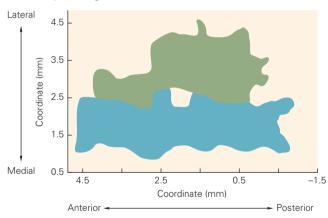

B. The areas of the motor output map from which the trained movements can be evoked parallel the level of performance (number of successful pellet retrievals) during acquisition of the motor skill and extinction (due to lack of practice). Two areas were tested: a "dual response" area (left plot), from which any combination of finger and wrist motions could be evoked, and an area from which the specific combination of finger flexion and wrist extension could be evoked (right plot). Both areas increased as the monkey's skill improved with practice and decreased as the monkey's skill was extinguished through lack of practice. These data are from a different monkey than the one in part A but one that was trained in the same task.

В

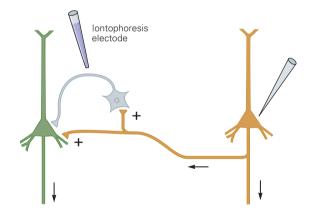

Figure 37–17 The functional organization of the motor map of a rat changes rapidly after transection of the facial nerve. (Reproduced, with permission, from Sanes et al. 1988 and from Jacobs and Donoghue 1991.)

A. A surface view of the rat's frontal cortex shows the normal somatotopic arrangement of areas representing forelimb, whisker, and periocular muscles. Within minutes after transection of the branches of the facial nerve that innervate whiskers, stimulation of cortical sites that formerly activated whisker muscles causes contraction of forelimb and periocular muscles.

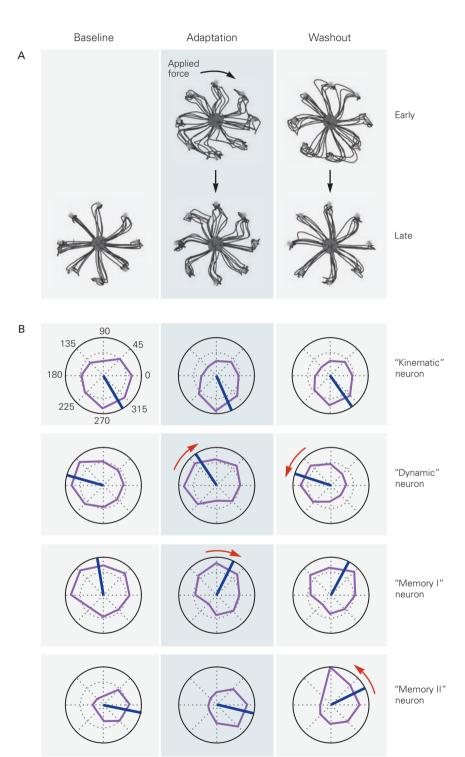

B. Elimination of the sensory inputs after transection of the facial nerve may lead to rapid changes in the balance of local

inhibitory circuits in the motor cortex. Under normal conditions (top) the excitatory effect of horizontal axonal projections between different parts of the motor map is subject to inhibition mediated by local inhibitory interneurons, so that electrical stimulation of a whisker site evokes contractions of only whisker muscles and not forelimb muscles. Iontophoretic injection of bicuculline into a forelimb site in the motor map blocks local GABA-mediated inhibition (bottom). As a result, stimulation of whisker sites can excite output neurons in forelimb and periocular sites through horizontal axonal collaterals whose influence is normally restricted by inhibitory interneurons.

Figure 37–18 Different motor cortex neurons may contribute to different aspects of adaptation to an external force field.

A. The records depict the hand paths of reaching movements from a central position to eight peripheral targets prior to and during adaptation to an external force field and then during the return to original baseline conditions. Paths are generally straight when no external force field is applied during reaching to the targets (late baseline). When a viscous curl field pushes the arm in the clockwise direction (arrow) hand paths are initially curved in the clockwise direction (early adaptation). After approximately 150 trials the paths become much straighter, indicating that the subject has learned to correct for the perturbing effect of the external force field (late adaptation). When the external field is abruptly removed, the paths in the first few trials are curved in the opposite direction (early washout), indicating that the exposure to the force field had led to a change in the subject's internal model of the environment to reflect the presence of the field. It takes several trials in the original conditions before the after-effect of the learning episode is no longer evident in hand kinematics (late washout). (Adapted, with permission, from Padoa-Schioppa, Li, and Bizzi 2004.)

B. Response patterns of four motor cortex neurons during and after adaptation to arm movement in a viscous curl field. All four neurons were directionally tuned in the baseline conditions (left column). The tuning of some neurons changed only during adaptation ("memory I" neuron); only during washout, that is, readaptation to the baseline conditions ("memory II" neuron); or both ("dynamic" neuron). Muscles showed the same pattern of responses as the "dynamic" neuron, implicating this neuron in the control of the forces needed to compensate for the field. (Adapted, with permission, from Li, Padoa-Schioppa, and Bizzi 2001.)

to be located in several brain structures, including the cerebellum, superior parietal cortex, premotor cortex, and primary motor cortex.

Emilio Bizzi and colleagues recorded the activity of the same primary motor cortex neurons over several hours in monkeys as the animals first made arm movements without an external force field, then while they made many movements to adapt to a viscous curl field, and finally while they readapted to the baseline condition (the "washout" period). As the monkeys adapted to the force field the directional tuning of many neurons gradually changed by 15 to 20 degrees from what it was before exposure to the viscous curl field, and then rotated back to the baseline during the washout period (Figure 37-18B). Arm muscles showed similar changes during adaptation and washout, implicating those neurons in the incremental adaptation of the motor command to the external curl field. Other neurons did not change directionality during either adaptation or washout, as if their signals communicated the desired movement kinematics across all force-field conditions.

Two other groups of neurons showed special properties. The directional tuning of one group changed when the monkeys switched from the null field to the curl field but did not return to baseline during washout (Figure 37–18B). The other group did not change during the original adaptation from null field to curl field but changed during washout. Bizzi proposed that these two groups of neurons retain the memory of one or the other of the successive learning episodes—adaptation and washout—in the task. That is, even though the motor performance of the monkeys returned to baseline, the functional state of the primary motor cortex did not revert to its original condition—a trace of the recent learning history persisted in the altered tuning properties of some neurons.

These and similar findings from other studies suggest that the motor map of the primary motor cortex is not static. Instead, the neuronal circuitry creates a dynamic, adaptive map that generates the motor commands required to accomplish desired actions under different conditions. This strongly implicates the primary motor cortex in the acquisition, retention, and recall of procedural skills, but does not clarify whether it functions primarily as part of a feedback controller, as an inverse internal model for task dynamics, or both.

Furthermore, recent studies have found that adaptive changes in motor cortex activity lag the improvement in motor performance by several trials during adaptation. This suggests that learning-related adjustments to motor commands are initially made elsewhere, with the cerebellum as one strong candidate.

The primary motor cortex may thus be more strongly involved in the slower processes of long-term retention and recall of motor skills rather than the initial phase of learning a new skill.

An Overall View

The discovery of a topographically organized map of motor outputs to different parts of the body within a limited area of the cerebral cortex provided the first compelling experimental evidence for the cortical localization of motor function. For many years thereafter the role of the motor cortex was relegated to that of a simple map of muscles and muscle activity patterns by which the rest of the cerebral cortex controlled spinal motor neurons. Terms such as "upper-motorneuron disease" were common in the clinical literature of an earlier era, but this view of motor cortex function is simplistic and incorrect.

Although the motor cortex does play a critical role in the control of voluntary movements, its neurons do not function like spinal motor neurons whose sole role is to encode muscle activity patterns. Instead, the motor cortex contains a heterogeneous population of neurons that contribute to the several operations required to convert a plan of action into the motor commands that execute the plan. The novel evolutionary development in primates of a direct, monosynaptic projection onto spinal motor neurons enables the primary motor cortex to control movements of the hand and fingers in a uniquely skillful way. This feature has been critical in the acquisition of dexterous hand movements that only higher primates and especially humans possess.

The primary motor cortex is part of a distributed network of cortical motor areas, each with its own role in voluntary motor control. The primary motor cortex should be regarded as a dynamic computational map whose internal organization and spinal connections convert central signals about motor intentions and sensory feedback about the current state of the limb into motor output commands, rather than as a static map of specific muscles or movements of body parts. The motor cortex also provides a substrate for adaptive alterations during the acquisition of motor skills and the recovery of function after lesions.

Voluntary Movement: The Parietal and Premotor Cortex

Voluntary Movement Expresses an Intention to Act

Voluntary Movement Requires Sensory Information About the World and the Body

Reaching for an Object Requires Sensory Information About the Object's Location in Space

Space Is Represented in Several Cortical Areas with Different Sensory and Motor Properties

The Inferior Parietal and Ventral Premotor Cortex Contain Representations of Peripersonal Space

The Superior Parietal Cortex Uses Sensory Information to Guide Arm Movements Toward Objects in Peripersonal Space

Premotor and Primary Motor Cortex Formulate More Specific Motor Plans About Intended Reaching Movements

Grasping an Object Requires Sensory Information About Its Physical Properties

Neurons in the Inferior Parietal Cortex Associate the Physical Properties of an Object with Specific Motor Acts

The Activity of Neurons of the Inferior Parietal Cortex Is Influenced by the Purpose of an Action

The Activity of Neurons in the Ventral Premotor Cortex Correlates with Motor Acts

The Primary Motor Cortex Transforms a Grasping Action Plan into Appropriate Finger Movements

The Supplementary Motor Complex Plays a Crucial Role in Selecting and Executing Appropriate Voluntary Actions

The Cortical Motor System Is Involved in Planning Action

Cortical Motor Areas Apply the Rules That Govern Behavior

The Premotor Cortex Contributes to Perceptual Decisions That Guide Motor Behavior

The Premotor Cortex Is Involved in Learning Motor Skills

Cortical Motor Areas Contribute to Understanding the Observed Actions of Others

The Relationship between Motor Acts, the Sense of Volition, and Free Will Is Uncertain

An Overall View

In this chapter we describe how the cerebral cortex uses sensory information about the external world in deciding on which actions to take and how to organize voluntary movements to accomplish those actions. Studies over the past 25 years have shown that the cortical motor system is not an unthinking, passive circuit controlled by more intelligent parts of the brain. Instead, it is intimately involved in the many interrelated neural processes required to choose a plan of action, including processes that appear to be more perceptual and cognitive than motor in nature. The motor system also contributes to cognitive processes that appear unrelated to motor control, such as understanding the actions of others and the potential outcomes of observed events.

Voluntary Movement Expresses an Intention to Act

Voluntary behavior is the physical expression of an intention to act on the environment to achieve a goal. Let us say you want a cup of coffee. There may be many reasons why: You may wish to enjoy the stimulating effect of caffeine or may simply be thirsty. Whatever

its origin, your behavioral goal is established by your motivational state but is fulfilled by voluntary motor behavior. The motor system has to transform your intention into action.

How you achieve your goal depends on the circumstances in which you find yourself. If the cup of coffee is already prepared and sitting in front of you, you can simply reach out, grasp the cup, and bring it to your lips. Often, however, the situation is more complex. The coffee might not be ready, or you might not have any coffee at home. In this case, to satisfy your craving for coffee you must organize and perform a complex series of actions to fulfill your goal of drinking coffee. You may go out to buy the coffee and return home, or you may go to a café, order a coffee, and drink it there. Alternatively, if it is too late in the evening or if the weather is inclement, you may alter your goal, such as drinking tea instead of coffee.

Each of these different voluntary behaviors is an action that serves an intermediate goal. However, only the entire series of actions can achieve your ultimate goal. The capacity to maintain a behavioral goal during a series of actions, and to develop alternative behavioral strategies and action sequences to fulfill the goal, are hallmarks of voluntary behavior. The prefrontal cortex located rostral to the motor areas plays a critical role in the organization of voluntary behavior. Here we focus on the neuronal mechanisms in the parietal and premotor cortex that mediate voluntary behaviors.

Voluntary behavior often involves physical interaction with objects in the external world. This requires the brain to convert sensory inputs about the state of the world and the individual's internal state into motor commands. As described in Chapter 33, the transformation involves a sequence of neural operations in many cortical and subcortical areas. No single area is responsible for all the steps between intention and action, or indeed for any one particular operation. This distributed organization is characteristic of all aspects of the neural control of voluntary behavior.

Another important feature of voluntary behavior is that once an intention is formed, action can be delayed or not performed at all. One is not irrevocably compelled to act on an intention the moment it is formed. A reflex, by contrast, is evoked immediately by a stimulus. Without self-control over whether, how, and when to act, behavior would be driven by the moment—impulsive, compulsive, and even antisocial. These considerations suggest that the motor system operates in at least two stages: movement planning and execution. Planning involves deciding what action

or series of actions to perform to fulfill an intention, whereas execution orchestrates actual movement.

Studies of nearly every cortical area involved in arm movement have attempted to identify the neural pathways specific to planning or execution. This is often done by imposing a delay between the instruction about what movement to make and the cue to execute it. These studies show that none of the cortical areas contains a homogeneous population of neurons dedicated only to planning or execution. Instead, a broad range of neuronal function is evident in each area. Some neurons respond only during the planning phase of the task, whereas others discharge during the execution phase. Still others show activity changes during both stages (Figure 38–1).

The major difference between cortical areas is whether the predominant neural activity is correlated with planning or execution. Whereas many primary motor cortex neurons discharge mainly during execution, premotor and parietal cortices contain more neurons that are strongly activated during the planning stage.

Neural activity during the planning stage also provides information about the intended act. The activity of single neurons and populations during the delay period of reach-to-grasp tasks conveys such information as the location of the target, the direction of arm movement, and the configuration of the hand required to grasp an object. This activity even encodes information about higher-order aspects of the action, such as its goal and expected reward value.

Even when a well-trained monkey makes the wrong movement in response to an instruction, the neural activity during the delay period before movement onset generally predicts the erroneous response. This is compelling evidence that the activity is a neural correlate of the intended motor act, not a passive sensory response to the stimulus that instructed it.

Further evidence of motor planning in the cortex comes from comparing the neural activity in a monkey when it has been instructed to make a reaching movement and when it has been instructed to withhold reaching. Many neurons in the premotor cortex generate directionally tuned activity during the delay period when the monkey is instructed to move, but not when it is instructed to refrain from moving. This differential activity represents an unequivocal signal about the monkey's intention either to reach in different directions or not to move in response to an instructional cue seconds before the action is executed (Figure 38–2).

These studies demonstrate that activity in several movement-related cortical areas signals information about the nature of an intended motor act

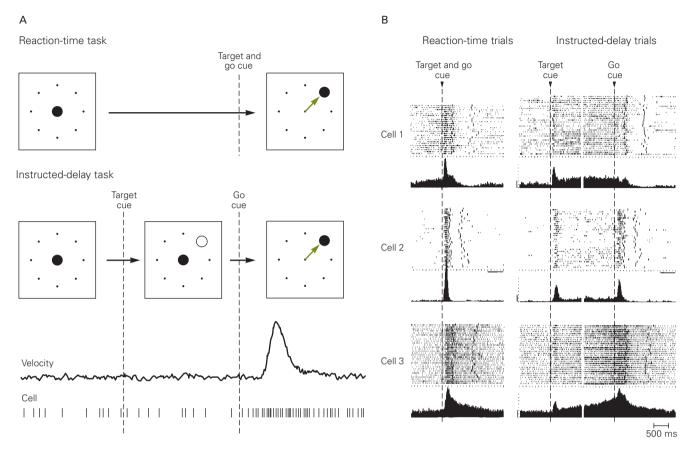

Figure 38–1 Neural processes related to movement planning and movement execution can be dissociated in time. (Reproduced, with permission, from Crammond and Kalaska 2000.)

A. In a reaction-time task a sensory cue instructs the subject both where to move (target cue) and when to move (go cue). All neuronal operations required to plan and initiate the execution of the movement are performed in the brief time between the appearance of the cue and the onset of movement. In an instructed-delay task an initial cue tells the subject where to move and only later is the cue given to start movement. The knowledge provided by the first cue permits the subject to plan the upcoming movement. Any changes in activity that occur after the first cue but before the second are presumed to be neuronal correlates of the planning stage.

B. Movement planning and execution are not completely segregated at the level of single neurons or neuronal populations in a given cortical area. Raster plots and cumulative

histograms show the responses of three premotor cortex neurons to movements in each cell's preferred direction during reaction-time trials and instructed-delay trials. In the raster plots each row represents activity in a single trial. The thin tics represent action potentials, and the two thicker tics show the time of movement onset and end. In reaction-time trials the monkey does not know in which direction to move until the target appears. In contrast, in instructed-delay trials an initial cue informs the monkey where the target lies well in advance of the appearance of a second signal to initiate the movement. During the delay period many premotor cells show directionally tuned changes in activity that signal the direction of the impending delayed movement. The activity in cell 1 appears to be strictly related to the planning phase of the task, for there is no execution-related activity after the go signal in the instructed-delay task. The other two cells show different degrees of activity related to both planning and execution.

well before execution of the act. Many neurons in the same cortical areas also discharge during movement execution, implicating those areas in the control of movement. Given this close anatomical proximity of planning- and execution-related activity, even at the level of individual neurons, a major unresolved

question is why planning-related neural activity does not immediately initiate the movement. There must exist a mechanism that either prevents movement execution during the delayed planning stage or permits the start of movement at a later time (see Box 38–2).

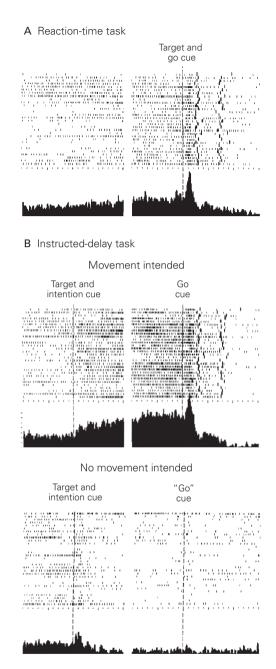

Figure 38–2 Decisions about response choices are evident in the activity of premotor cortex neurons. (Reproduced, with permission, from Crammond and Kalaska 2000.)

A. In a reaction-time task (reaching) a cell exhibits gradually increasing, nondirectional, tonic firing while waiting for the appearance of a target. When the target appears (**go cue**) the cell generates a directionally tuned response.

B. In an instructed-delay task, when a monkey is shown the target and instructed to move once the go cue appears, the cell generates a strong, directionally tuned signal for the duration of the delay period before the go cue. When the monkey is shown the target but is instructed not to move when the go cue appears, the cell's activity decreases.

Voluntary Movement Requires Sensory Information About the World and the Body

Let us return to the action of getting a cup of coffee. The deceptively simple action of drinking from a cup represents not a single motor act but a series of motor acts, each with a specific goal: reaching for the cup, grasping, lifting, holding, and bringing the cup to the mouth. The sequence of acts must be coordinated so that the arm and hand can interact physically with the cup in an efficient manner to achieve the desired goal.

To reach out and grasp the cup the motor system must solve two basic problems. First, it has to localize the cup in space and transform this location into a reaching movement of the arm to bring the hand to the cup. Second, it must encode the physical properties of the cup, such as its size and shape, and transform them into a particular grip. One might suppose that reaching and grasping are conducted sequentially. However, recordings of hand and arm kinematics show that this is not so: The two acts occur largely simultaneously. As the arm reaches toward the cup, the hand starts to rotate and open to match the size, shape, and orientation of the target. The hand and fingers then begin to close even before the hand contacts the cup. Furthermore, although the two processes occur in parallel, they can influence each other. Both the velocity and acceleration of grasping and reaching, for example, can depend on the location, distance, orientation, size, and shape of the object to be lifted.

Along with information about the target object the motor system requires information about the current status of the arm, including its posture and motion and the position of the hand relative to the target. The various brain operations required to plan and guide arm movements are implemented in part by interconnected populations of neurons in the primary motor cortex, premotor cortex, and parietal cortex.

The parietal lobe is the principal target of the dorsal visual stream. It has long been implicated in a variety of functions such as the perception of the spatial structure of the world and the control of directed attention. As a result, the dorsal visual stream is often called the "where" pathway to distinguish it from the "what" pathway, the ventral visual stream that projects from the primary visual cortex into the temporal lobe and is involved in the recognition of objects.

Pioneering neurophysiological studies of the parietal lobe in active monkeys conducted independently by Vernon Mountcastle and Juhani Hyvärinen and their colleagues in the 1970s showed that many parietal neurons also discharge during eye, arm, or hand

movements when an animal attentively explores and interacts with its environment. One striking property that both groups observed is that the discharge of many parietal neurons is highly dependent on the goal of the behavior. Neurons discharge strongly when a monkey reaches to grasp an object, searches for an object in a box, or manipulates an object with its hand, but are much less active when the monkey makes other arm and hand movements.

More recently, behavioral studies by Mel Goodale and David Milner and their collaborators have led to an important and still controversial hypothesis about the role of the dorsal visual stream. They propose that a primary function of the parietal lobe is to extract sensory information about the external world and one's own body that is useful for the planning and guidance of movements. This sensory guidance of action may operate in parallel with and independently of perceptual processes evoked by the same sensory inputs. For instance, whereas our perception of the size and orientation of objects can be deceived by certain visual illusions, the motor system often behaves as if it is not fooled and makes accurate movements (Figure 38-3). As a result, the dorsal visual stream is also called the "how" pathway (see Chapter 18).

This does not mean, however, that the parietal lobe has no role in spatial perception or attention. On the contrary, we now recognize that its contributions to spatial perception, attention, and sensorimotor transformations are intimately intertwined. This interconnectedness of function is clear in an examination of how different parts of the parietal lobe and associated precentral motor areas contribute to the planning and execution of the reach-to-grasp action required to drink a cup of coffee.

Reaching for an Object Requires Sensory Information About the Object's Location in Space

Although we describe the neural processes underlying reach and grasp separately, the two actions are usually coordinated. Coordination is achieved through reciprocal axonal connections between reach- and grasp-related populations both within the same cortical areas and between different areas and through populations of neurons that discharge in connection with components of both reach and grasp.

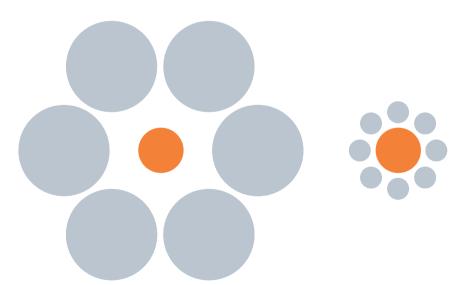

Figure 38–3 The visual information that serves object perception and movement may be processed in distinct, parallel pathways. In the Ebbinghaus illusion two orange disks of identical diameter appear to be of different size because one is surrounded by large disks and the other by small disks. Mel Goodale and collaborators reported that when subjects were asked to indicate the size of the central disks with their thumb and index finger, the separation between finger

and thumb was significantly larger for the disk on the right. However, when subjects reached out to grasp the identical disks surrounded by larger or smaller disks, their thumb-finger separation was nearly the same in both cases. This and similar evidence suggests that visual pathways to the parietal lobe are distinct from those that support object perception and that the parietal inputs are not solely the output of the perceptual pathways.

Space Is Represented in Several Cortical Areas with Different Sensory and Motor Properties

The planning of a reaching movement is usually defined as the neural process by which the location of an object in space is translated into an arm movement that brings the hand into contact with the object. Our intuitive conception of space as a single continuous expanse—one that extends in all directions and within which objects have locations relative to one another and to ourselves—has long influenced neuroscience.

According to classical neurology the neural counterpart of the space that we experience is a single map in the parietal lobe constructed by inputs from different sensory modalities. This unified, multimodal neural replica of the world is assumed to provide all the information necessary for acting on an object and is shared by the different motor circuits that control the eyes, arm, hand, and other effectors.

An alternative view is that there are many maps each related to a different motor effector and adapted to its specific needs. These spatial representations are created when the individual interacts with its environment, defining a series of motor relations determined by the properties of a particular effector. For example, a rodent has a locomotion map in the hippocampus and adjacent entorhinal cortex representing the animal's current location and direction of motion. This alternative hypothesis suggests that our intuitive sense of space arises at least in part from our motor interactions with the world.

Evidence collected in recent years clearly does not support the notion of a single topographically organized representation of space in the parietal cortex. First, the parietal cortex is organized as a series of areas working in parallel. Second, *near space* or *peripersonal space*, the space within our reach, is encoded in areas different from those that represent *far space*, the space beyond our reach. Third, the functional properties of the neurons in parietal and frontal areas of cortex involved in spatial coding vary depending on the body part controlled, such as the eyes versus the arm.

These findings support the idea there are many spatial maps, some located in the parietal cortex and others in the frontal cortex, whose properties are tuned to the motor requirements of different effectors. Moreover, the spatial maps in each cortical area are not maps in the usual sense of a faithful point-to-point representation of surrounding space, but rather dynamic maps that may expand or shrink according to the motor requirements necessary to interact with a given stationary or moving object.

The Inferior Parietal and Ventral Premotor Cortex Contain Representations of Peripersonal Space

In monkeys several areas in the inferior parietal cortex and interconnected parts of the premotor cortex contain representations of peripersonal space. One such area, the ventral intraparietal area, is located in the fundus of the intraparietal sulcus (Figure 38–4A). It receives visual projections from components of the dorsal visual stream, including areas MST (medial superior temporal cortex) and MT (medial temporal cortex), that are involved in the analysis of optic flow and visual motion.

Some ventral intraparietal neurons respond only to visual stimuli and respond preferentially either to expanding (looming) or contracting (receding) stimuli or to stimuli moving in the horizontal or vertical plane. Others have polymodal receptive fields within which inputs from different sensory modalities lie in spatial register (Figure 38-5A). These neurons respond to tactile stimuli, most often near the mouth or on the face but also on the arm or trunk, as well as to visual stimuli located immediately adjacent to the tactile receptive field. Some even respond to auditory stimuli in the same spatial location. Certain polymodal neurons respond to both visual and tactile stimuli moving in the same direction whereas others are strongly activated by visual stimuli that move toward their tactile receptive field but only if the path of motion will eventually intersect the tactile receptive field.

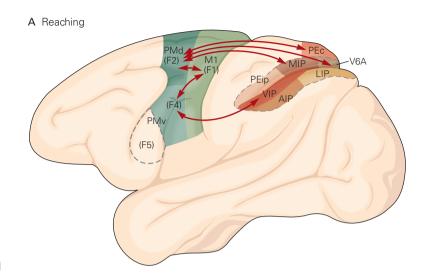

Ventral intraparietal neurons appear to represent an early stage in the construction of a peripersonal spatial map that is more fully expressed in a caudal part of the ventral premotor cortex, area F4, with which it is strongly interconnected. Virtually all neurons in area F4 respond to somatosensory inputs, especially tactile stimuli. The tactile receptive fields are located primarily on the face, neck, arms, and hands. Half of the neurons also respond to visual stimuli and a few to auditory stimuli.

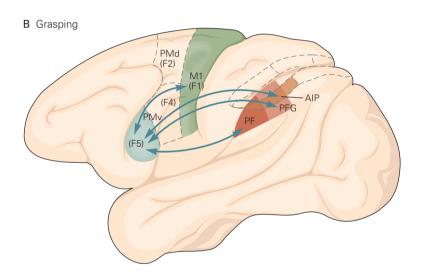

As with ventral intraparietal neurons, the modality-specific receptive fields in area F4 lie in register (Figure 38–5B). This suggests that the visual receptive fields are not defined by the location of the visual stimulus on the retina, as in most neurons in the visual cortex, but are anchored to specific parts of the individual's body. One striking feature of such a polymodal neuron, especially in the ventral premotor cortex, is that its visual receptive field remains aligned with the tactile receptive field when the monkey looks in different directions, but moves with the tactile receptive field to a different part of peripersonal space when the monkey moves the corresponding part of its body.

Figure 38–4 Separate parietofrontal pathways are involved in the visuomotor transformations for reaching and grasping.

A. The visuomotor transformation necessary for reaching is mediated by the parietofrontal network shown here. The areas located within the intraparietal sulcus are shown in an unfolded view of the sulcus. Two serial pathways are involved in the organization of reaching movements. The ventral stream has its principal nodes in the ventral intraparietal area (VIP) and area F4 of the ventral premotor cortex, whereas the dorsal stream has synaptic relays in the superior parietal lobe (MIP, V6A) and the dorsal premotor cortex (PMd), which includes area F2. (Parietal areas include AIP, anterior intraparietal area; LIP, lateral intraparietal area; and V6A, the parietal portion of the parieto-occipital area.) PEc and PEip are parietal areas according to the nomenclature of von Economo. Somatosensory areas 1, 2, and 3 and area PE, which provide somatosensory input to M1 (F1), are not shown in the figure. Precentral areas include F5, a subdivision of PMv, the ventral premotor cortex, and the primary motor cortex (M1, F1).

B. The visuomotor transformation necessary for grasping is mediated by the parietofrontal network shown here. The AIP and PFG areas are concerned mostly with hand movements, whereas area PF is concerned with mouth movements. PF and PFG are parietal areas according to the nomenclature of von Economo. Area F5 in PMv is concerned with both hand and mouth motor acts. Some grasping neurons have been found in F2, the ventral part of PMd. Area M1 (or F1) contains a large sector that controls the fingers, hand, and wrist (see Figure 37–2A). Other abbreviations are explained in part A.

Nevertheless, area F4 is a motor area and its neurons also discharge in association with movements, most often of the arm, wrist, neck, and face. The neurons in this area control movements of the head and arm toward different parts of the body, or toward objects close to the body, to permit the animal to grasp them with its mouth or hand. Some neurons discharge during the entire action of bringing the hand to the mouth and opening the mouth to ingest food, as well as during arm reaching and associated neck- and trunk-orienting movements. Activity in other neurons is correlated not only with reaching but also with other behaviors such as the avoidance of threatening stimuli. The sensory representation of peripersonal space in area F4 contributes to the planning and execution of those behaviors.

The Superior Parietal Cortex Uses Sensory Information to Guide Arm Movements Toward Objects in Peripersonal Space

A key requirement for efficient reaching is knowledge of where the arm is before and during the action. Lesion studies suggest that this information is represented in Brodmann's area 2, the primary somatosensory area (S-I), and in the superior parietal lobule. Patients with lesions of these regions are unable to reach toward objects efficiently, even though they do not have the deficits of spatial perception, such as spatial neglect, that are typical of lesions in the inferior parietal lobe (see Chapter 19).

Although single-neuron studies confirm the role of these areas in providing information about arm

A Receptive fields of neurons in ventral intraparietal cortex (VIP)

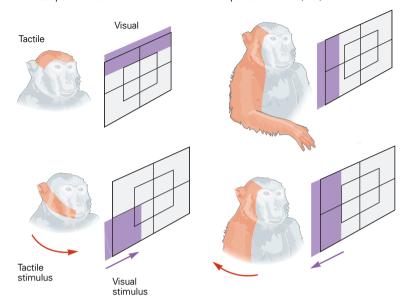

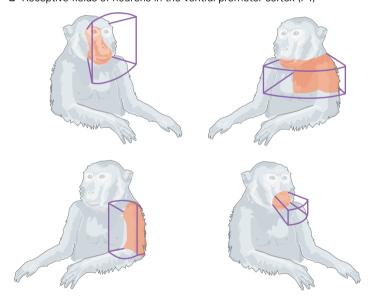

Figure 38–5 Some neurons in the parietal and premotor cortex respond to both tactile and visual stimuli within receptive fields that are spatially in register.

A. Some neurons in the ventral intraparietal cortex have tactile and visual receptive fields that are aligned in a congruent manner. Orange areas on the monkey represent tactile receptive fields; purple areas on the screen in front of the monkey's face and centered on its nose represent visual receptive fields. Many of the neurons also share directional preferences for movement of tactile and visual stimuli (arrows). (Reproduced, with permission, from Duhamel, Colby, and Goldberg 1998.)

B. Neurons in ventral premotor cortex area F4 respond to either tactile or visual stimulation.

Orange areas are tactile receptive fields; purple lines indicate the three-dimensional receptive fields within which visual stimuli activate the neuron. (Reproduced, with permission, from Fogassi et al. 1996.)

B Receptive fields of neurons in the ventral premotor cortex (F4)

location, there are clear functional differences between the two areas. Neurons in area 2 usually respond to tactile input from a limited part of the body or to movements of a single joint or a few adjacent joints in specific directions and most commonly on the contralateral side of the body. In contrast, many neurons in the superior parietal lobule discharge during combined movements of multiple joints, the assumption of specific postures, or movements of the limbs and the body. Some cells also respond during combined movements of the arms and hind limbs or bilateral movements of both arms.

These findings indicate that, unlike neurons in area 2 that encode the positions and movements of specific parts of the body, neurons in the superior parietal lobe integrate information on the positions of individual joints as well as the positions of limb segments with respect to the body. This integration creates a

body schema that provides information on where the arm is located with respect to the body and how the different arm segments are positioned with respect to one another. This schema provides fundamental information for the proprioceptive guidance of arm movements.

More posterior and medial sectors of the superior parietal cortex also receive input from areas V2 and V3 of the extrastriate visual cortex. Important nodes in this network include areas V6A and PEc and an area of parietal cortex involved in reaching described by Richard Andersen and colleagues and which most likely corresponds to the medial intraparietal area (MIP) and nearby parts of the superior and inferior parietal cortex (see Figure 38-4A). In these areas the spatial representation for reaching is not based on body-centered coordinates. For example, neurons in V6A and PEc often signal the retinal location of possible targets for reaching, but their activity is also strongly modulated by complex combinations of inputs related to the direction of gaze and the current arm posture and hand position.

Andersen and his associates propose that the reach-related region of parietal cortex is particularly important for specifying the goal or target of reaching but not how the action should be performed. The activity of many neurons in this area varies with the location of the target relative to the hand. Remarkably, however, this motor error signal is not centered on the current location of the hand or target but rather on the current direction of gaze. Each time the monkey looks in a different direction the reach-related activity in the neurons changes (Figure 38–6). In contrast, the reach-related activity of many neurons in area PEip is less gaze-centered and more related to the current hand position and arm posture.

Another important property of neurons in the parietal reach region is that they respond not only to passive sensory inputs but also before the onset of movements and during the planning period of delayed-reaching tasks. This behavior indicates that these neurons receive centrally generated signals about motor intentions prior to movement onset, likely through their reciprocal connections with precentral motor areas. Recent theoretical and experimental findings suggest that this combination of peripheral sensory and central motor inputs permits the parietal reach region to integrate sensory input with efference copies of outgoing motor commands to compute a continuously updated estimate of the current arm state and a prediction about how the arm will respond to the motor command. This forward internal model of the arm could be used to make rapid

corrections for errors in ongoing arm movements and to acquire motor skills.

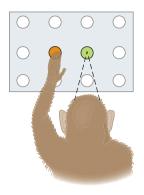

The functional properties of areas in the superior parietal cortex concerned with reaching suggest an intriguing explanation of the clinical phenomenon of optic ataxia. Patients with a lesion of the superior parietal cortex have difficulty with visually guided arm movements toward an object. Making errors in the frontal or sagittal plane, the arm gropes for the target until it encounters the object almost by chance. The deficit is severe when the target is in the peripheral part of the visual field, less when the target lies in the parafoveal region, and negligible when the patient fixates the target. The symptoms of optic ataxia may result from failure of the neural circuits that convert sensory information about targets and the arm into motor plans or from failure of the circuits that contribute to a predictive forward model of the arm's current state.

Premotor and Primary Motor Cortex Formulate More Specific Motor Plans About Intended Reaching Movements

The reach-related areas of the parietal cortex are reciprocally connected to several precentral motor areas, including the primary motor cortex, dorsal and ventral premotor cortex, and supplementary motor area. Neurons in all of these areas contribute to sensorimotor transformations that provide increasingly detailed information about the desired spatial kinematics and causal mechanical details of the movements.

For example, the reach-related neurons in the dorsal premotor cortex are much less strongly influenced by the direction of gaze than are neurons in the parietal reach area. Instead they are driven by the direction of the intended reaching movements during the planning period of delayed-reaching tasks and during the reaching movement itself. Furthermore, during the planning period many dorsal premotor neurons signal the direction of movement to the target whether the left or right arm is used to reach for the target (Figure 38–7). This finding suggests that the premotor neurons represent the appropriate extrinsic spatial kinematics of the reaching movement independent of the arm that will perform it. In contrast, the activity of most reach-related neurons in the primary motor cortex is related to movement of the contralateral arm.

In other studies a monkey was trained to make arm movements to move a cursor on a computer monitor. In some trials the motions of the arm and cursor were collinear. In other trials they were decoupled in

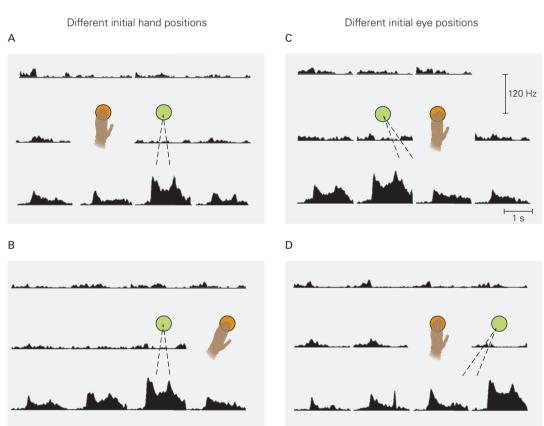

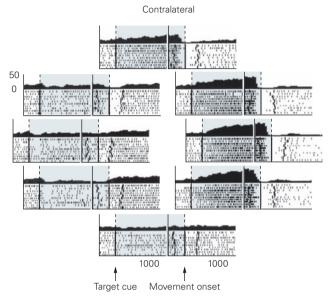

Figure 38–6 Neurons in the parietal reach area encode target location in eye-centered coordinates. An upright board contains an array of pushbuttons. The four panels show the possible behavioral conditions at the beginning of a trial. The initial hand position and point of visual fixation are indicated by the green and orange buttons, respectively. Histograms of activity in a single neuron are arranged to correspond to the locations of the buttons on the board that serve as the target

of a reaching movement from the start position in different trials. The firing pattern of this neuron does not vary with changes in initial limb position (A, B), but shifts with a change in the initial direction of gaze (C, D). The neuron thus signals the target location relative to the current direction of gaze, independent of the direction of arm movement required to reach the target. (Modified, with permission, from Andersen and Buneo 2002.)

A Dorsal premotor cortex neuron

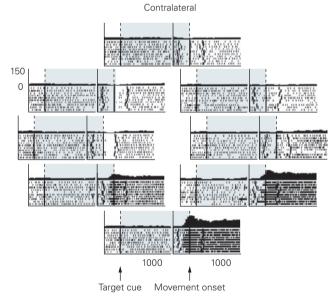

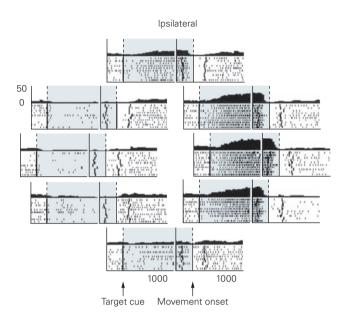

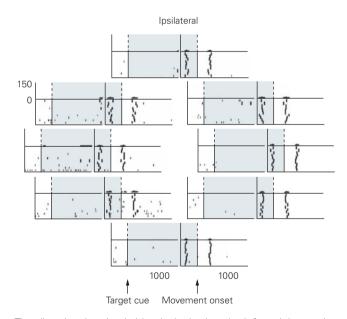

Figure 38–7 Reaching movement is represented differently in the premotor and primary motor cortex during planning and execution of the movement. (Modified, with permission, from Cisek, Crammond, and Kalaska 2003.)

A. Activity of a dorsal premotor cortex neuron in a monkey during an instructed-delay reaching task. The animal is trained to reach for targets in eight directions from a central starting position using either arm. During testing one arm is contralateral and one arm is ipsilateral to the recording site. During the planning period—the time between the presentation of the target cue and the delayed onset of movement—the neuron is directionally tuned with a preference for rightward movements.

The directional tuning is identical whether the left or right arm is used. The neuron is relatively inactive during movement execution. In each raster plot the left vertical line indicates presentation of the target cue, and the right vertical line indicates the onset of arm movement. The thick tics to the left and right of the movement-onset line in each trial indicate, respectively, presentation of the go cue and the end of movement.

B. Activity of a primary motor cortex neuron during the same task as in part A. The neuron is strongly active and directionally tuned toward the lower targets when the contralateral arm is used but only during the execution phase. It is essentially inactive when the ipsilateral arm is used.

Box 38–1 The Cortical Motor System Does Not Solve Newtonian Equations

Understanding the cortical mechanisms underlying the planning and execution of reaching movements requires insight into how single neurons and neuronal populations encode different properties of intended movements and how they transform that information into motor commands.

For many years the study of the cerebral cortical mechanisms of motor control has been guided by terminology and concepts borrowed from physics, engineering, and control theory. Many studies have therefore sought and found statistical correlations between the activity of neurons in movement-related cortical areas and such movement-related parameters as target location, the velocities of hand displacement and reach trajectory, motor output force, and joint torque.

It is unlikely, however, that the motor system controls movements by encoding them in the familiar but

arbitrary terms of Newtonian mechanics or by solving equations derived from the Newtonian laws of motion. Even though neural responses are consistent with a sequence of sensorimotor transformations, it is improbable that neural circuits explicitly solve the trigonometric and algebraic equations that define those transformations.

The cortical mechanisms for the planning and control of reaching movements are not based on the formalisms and first principles of physics, mechanics, and mathematics. They are determined by the stream of signals provided by peripheral sensors, by the force-generating properties of muscles, by the emergent dynamic mechanical properties of the arm, and by the properties of the spinal motor circuitry that converts the descending motor commands into muscle activity and movements.

one of three ways: by rotating the cursor motion at a 90 degree angle to the arm movement, applying a mirror-image transformation, or requiring the monkey to make elliptical motions of its arm to draw a circle with the cursor. Some neurons, especially in the primary motor cortex, signaled the motions of the arm in both the collinear and decoupled conditions. Other neurons concentrated in the dorsal and ventral premotor cortex signaled the desired motions of the cursor under the different visuomotor conditions.

These findings indicate that premotor cortex neurons can generate an abstract representation of the goal of the motor output, in this case the motion of the cursor that the monkey was moving, independent of the arm movements that control the cursor's motion. Other neurons in the premotor and primary motor cortex translate that abstract representation into signals about what the arm must do to produce the desired cursor movements.

Although these results suggest that the motor system initially plans reaching movements in extrinsic spatial coordinates, we move by contracting muscles. Many neurophysiological studies have therefore sought the neural correlates of the transformation of a desired spatiotemporal movement pattern into its causal forces and muscle activity. The consensus is that the primary motor cortex plays an important role in that transformation (see Chapter 37). However, the

final motor command for the muscle-activity patterns required to execute the desired reaching movement is probably generated by spinal motor circuits.

In summary, neurophysiological studies have provided support for the general hypothesis that reaching movements involve neuronal processes that implement a sequence of transformations between sensory input and motor output. These processes occur in a dynamic, distributed network of cortical areas rather than in a strictly serial pathway. There are no abrupt transitions of cellular properties between cortical areas; instead there is a progression. Neural correlates of each putative transformation can be seen in both parietal and precentral areas, whose true nature and functions are still not fully known (Box 38–1).

Grasping an Object Requires Sensory Information About Its Physical Properties

At the same time as neural populations in several areas of the parietal and precentral cortex are controlling the reaching movement to bring your hand into proximity with a coffee cup, neural populations in several other overlapping and adjacent parietal and precentral areas are preparing the hand to grasp and lift the cup. These areas include the anterior intraparietal area (AIP) and area PFG of the rostral inferior parietal cortex, the

ventral premotor cortex, and the large central core of the arm's motor map in the primary motor cortex (see Figure 38–4B).

We have seen how the planning and control of the reaching movement involves a sequence of sensorimotor transformations that convert input about the spatial location of the coffee cup into a motor command to move the hand to the cup. The sensorimotor transformation involved in grasping the coffee cup is somewhat different. The sensorimotor system for the hand must possess a mechanism that can match the configuration of the hand and fingers and the grip forces exerted by the fingers to the physical properties of the cup. These include properties that you can see, such as the size, shape, and spatial orientation of the coffee cup. They can also include physical properties that have been learned through experience, such as the cup's expected weight and fragility and whether it contains hot or cold liquid. All of these factors influence how you use your hand to grasp and lift the cup.

To help understand how visual information about an object is transformed into specific movements to grasp and manipulate it, we shall speak of the affordances of an object, a concept introduced by James Gibson. When we observe an object our visual system automatically identifies the parts of it that allow for efficient manipulation of it. Those parts are not necessarily the features that permit recognition of the object, but rather those that afford specific opportunities for action. For example, the handle, body, and top of the coffee cup afford opportunities to grasp it. Any one affordance may be more appropriate in particular circumstances. If the cup is hot, for example, you will likely prefer to use the handle. If the handle is large, you may be able to insert all four fingers into it, but if it is small you may be able to use only one or two. If the coffee is not too hot, you may just as likely grasp the cup by its body or top.

Neurons in the Inferior Parietal Cortex Associate the Physical Properties of an Object with Specific Motor Acts

Beside being involved in the representation of space and the sensory guidance of reaching movements, the dorsal visual stream also provides the inferior parietal cortex with the visual information necessary for coding object affordances. The cortical processes that extract the affordances of observed objects and associate them with specific actions begin in the lateral and rostral part of the inferior parietal cortex, especially in the AIP and PFG areas (see Figure 38–4B).

The functional properties of neurons in AIP of the monkey have been investigated by Hideo Sakata and co-workers. They recorded the responses of neurons under three conditions: grasping objects in the light when they can be seen or in the dark when they cannot be seen, and merely observing the objects. The experiments showed that the neurons fall into three major categories: visually dominant, visuomotor, and motor-dominant neurons. Together these three classes of neurons contribute to neural operations that use visual input to encode the affordances of observed objects and associate them with appropriate motor acts.

Visual-dominant neurons discharge when the monkey fixates an object or grasps it in the light, but not when the monkey grasps an object in the dark (Figure 38–8). In contrast, motor-dominant neurons are active during grasping both in the light and in darkness. They are not active, however, during object fixation, indicating that they signal primarily the motor act of grasping, independent of visual input. Many visual-dominant and motor-dominant neurons respond selectively to objects of particular shapes such as spheres, rings, and flat disks, each of which requires a different type of grip.

Visuomotor neurons discharge when the monkey grasps objects, whether in the dark or in the light, but also during visual fixation. Individual visuomotor neurons additionally respond preferentially to shape: A neuron that becomes active when the monkey looks at a small disk also discharges when the monkey grasps the disk, but not when it grasps a sphere. This specificity to the shape of viewed objects indicates that these neurons link the affordances of an object to particular motor actions.

The Activity of Neurons of the Inferior Parietal Cortex Is Influenced by the Purpose of an Action

We often perform similar motor acts for different purposes. We pick up a coffee cup to drink from it or to wash it. The motor act of grasping is the same, but the objective is different.

As already noted, Mountcastle and Hyvärinen reported that the activation of many parietal neurons depends on the goal of the act being performed. More recently, Leonardo Fogassi and co-workers compared the firing patterns of grasp-related inferior parietal neurons under two conditions. In one the monkey grasped a piece of food and brought it to its mouth; in the other it placed the food into a container. The activity of many of the neurons varied with the task. Some were strongly active when the monkey picked up food

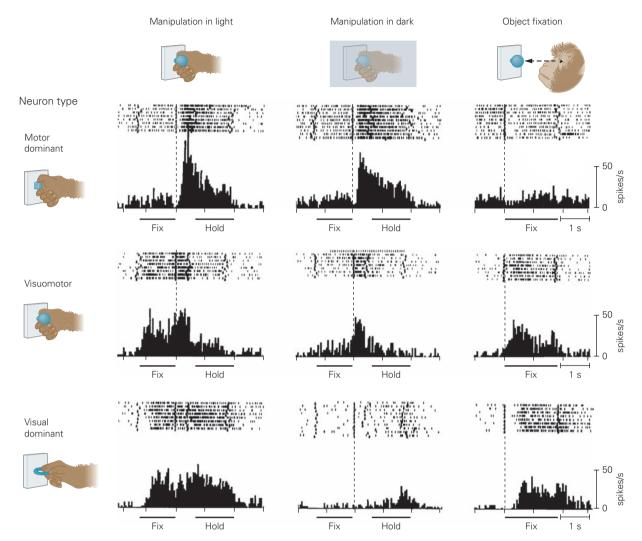

Figure 38–8 The three major categories of neurons in the anterior intraparietal area. A monkey sits in front of a dark box housing six distinct objects that are presented one at a time in a random order. Neural activity is tested during three behaviors: manipulation of the object in light, manipulation in the dark, and object fixation. The protocol for the manipulation in light begins with a red spot of light projected onto the object. The monkey fixates the spot of light and presses a lever that turns on a light inside the box that illuminates the object. After the monkey has held the lever for 1.0–1.2 s, the light changes to green, cuing the monkey to release the lever and grasp the object.

In the records shown here trials are aligned at the end of the visual fixation period and beginning of the reach-to-grasp period. The protocol for manipulation in the dark is similar except that all trials after the first are executed in darkness. In the object fixation protocol the green light cues the monkey to fixate the red spot of light and press the lever to illuminate the object; the animal then releases the lever but does not grasp the object. Trials are aligned at the beginning of the fixation period. The activity of different anterior intraparietal neurons shows differing degrees of dependence on the visual and motor components of this task. (Modified, with permission, from Murata et al. 2000.)

to bring it to the mouth, but only weakly excited when it picked up food to put it into a container. Others showed the opposite response (Figure 38–9). Factors such as grasping force, kinematics of reaching movements, and type of stimulus could not account for the context-specific activation of the neurons.

The Activity of Neurons in the Ventral Premotor Cortex Correlates with Motor Acts

The rostral part of the ventral premotor cortex, often called area F5, is reciprocally connected with the anterior intraparietal area, the rostral part of the

inferior parietal cortex, and the secondary somatosensory area. Functional mapping of area F5 based on electrical stimulation shows that this area contains representations of hand and mouth movements that overlap considerably.

Recording studies in monkeys indicate that the response properties of F5 neurons are elaborations of

the properties of neurons in the parietal regions that project into area F5. Unlike the anterior intraparietal area, however, F5 contains few or no visually dominant neurons. Murata and colleagues found that many neurons in area F5 discharge exclusively during the execution of certain motor acts, both in the light and in the dark. About 20% of the neurons, called *canonical neurons*, also

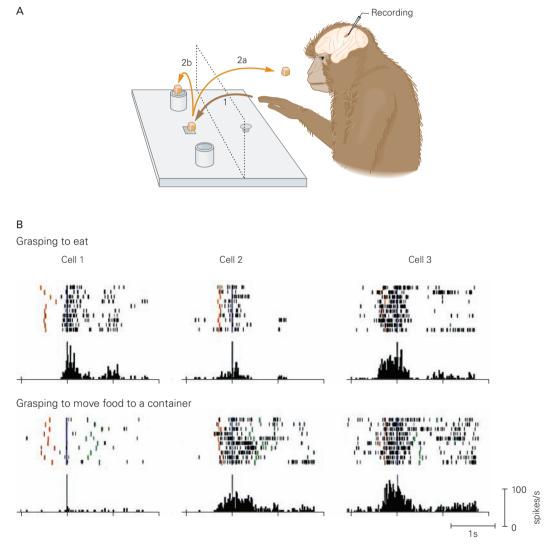

Figure 38–9 The activity of functionally distinct parietal motor neurons varies with the purpose of a grasping action. (Modified, with permission, from Fogassi et al. 2005.)

A. Apparatus and protocol for the experiment. A monkey is trained to press a button (start position) and reach and grasp a piece of food (1) either to bring it to the mouth (2a) or to place it into a container (2b). In the first condition the monkey eats the food brought to the mouth, whereas in the second it receives a food reward after the correct response.

B. Activity of three neurons in the inferior parietal cortex during the two actions. Cell 1 discharges more strongly when the monkey grasps the food to eat it than when it grasps the food simply to move it. The behavior of cell 2 is the opposite. Cell 3 shows no difference between the two actions. Raster plots and histograms are aligned with the moment when the monkey touches the object to be grasped. **Orange tics** indicate when the monkey releases its hand from the button at the starting position; **green tics** indicate when the hand touches the container.

respond to the sight of three-dimensional objects. They thus discharge whether the animal grasps an object or simply observes it and they show a preference for a particular type of grip (Figure 38–10).

The signal from a canonical neuron is identical whether the monkey observes or grasps an object. Thus when the cell is activated by the sight of an object, its activity signifies how to interact with the object. The activation of a canonical neuron does not automatically lead to overt action, for inhibitory control is exerted

by other neural circuits. Only when that inhibition is released does the internal representation become an overt action.

Another fundamental property of area F5 neurons is that their discharge correlates with the goal of a motor act and not with the individual movements forming it. Thus many neurons in F5 discharge when grasping is executed with effectors as different as the right hand, the left hand, and even the mouth. Conversely, an area F5 neuron may be active when an

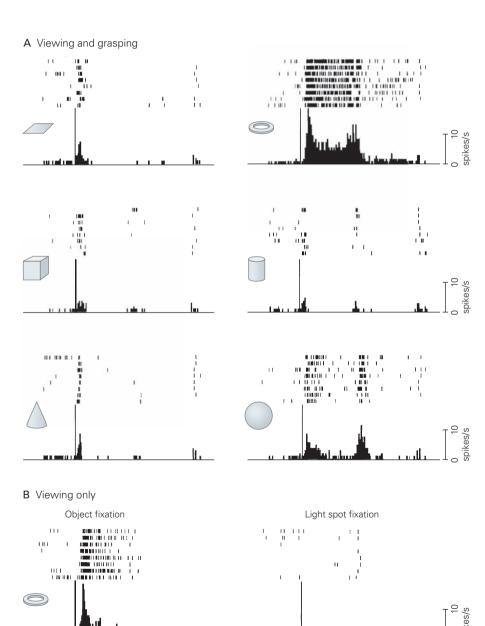

Figure 38–10 A canonical neuron in the ventral premotor cortex (area F5) of a monkey. (Reproduced, with permission, from Murata et al. 1997.)

A. The neuron's responses to viewing and grasping of six objects vary with the shape of the objects. The cell is more strongly activated by a ringshaped object than by other shapes.

B. The neuron responds when the animal fixates a ring-shaped object but not when the animal fixates a light spot. Raster plots and histograms are aligned (vertical bar) with the moment when the object becomes visible.

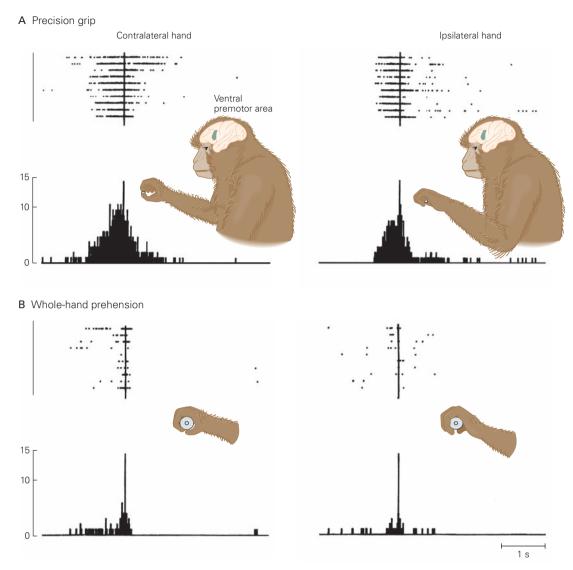

Figure 38–11 Some individual neurons in the ventral premotor cortex (area F5) of a monkey discharge selectively during one type of grasping. This neuron discharges vigorously during precision grip with either the right or the left hand but barely at all during whole-hand prehension with either

hand. Raster plots and histograms are aligned (vertical line) with the moment the monkey touches the food (A) or grasps the handle (B). (Reproduced, with permission, from Rizzolatti et al. 1988.)

index finger is flexed to grasp an object but not when the animal flexes the same finger to scratch itself. This property of grasp-related neurons in area F5 resembles that of many reach-related neurons in the dorsal premotor cortex.

Based on these properties, Giacomo Rizzolatti and co-workers subdivided F5 neurons into several functional classes that discharge preferentially during certain stereotypical hand actions, such as grasping, holding, tearing, or manipulating objects. In each of these classes many neurons discharge only if the monkey

uses a specific type of grip, such as precision grip, wholehand prehension, or finger prehension (Figure 38–11). Precision grip is the type most represented. Moreover, individual F5 neurons may discharge selectively at particular stages of one type of prehension. Some discharge throughout the entire action, others during the opening of the fingers, and still others during finger closure.

The view that the organization of area F5 is based on a repertory of motor acts has important implications. First, the existence of neurons that encode a limited range of specific motor acts is consistent with and may

account for the fact that we repeatedly interact with a particular object in a specific way. There exists in principle a very large number of possible ways to grasp an object, but we typically use only a few of them. We almost never use the fourth and fifth fingers to lift a cup of coffee, for example. The organization of area F5 allows the object affordances extracted by the anterior intraparietal area to be associated with appropriate motor actions. As we shall see later, this organization may also underlie the ability to recognize the goals of actions performed by others.

The Primary Motor Cortex Transforms a Grasping Action Plan into Appropriate Finger Movements

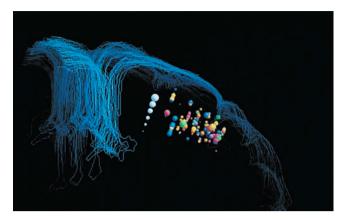

The ventral premotor cortex, including areas F4 and F5, projects to the hand and arm fields of the primary motor cortex. The primary motor cortex contains the largest and most detailed representation of finger and hand movements of all cortical motor areas (see Chapter 37).

Although some hand-related neurons in the primary motor cortex discharge in relation to the goal of a motor act rather than to specific movements, many others are active during finger or wrist movements across a broad range of grasping motions and object manipulation as well as during other activities. The grasp-selective input from premotor areas could facilitate the recruitment and organization of a set of neurons distributed across the motor map that controls a particular grasping action and matches it to an object's shape (Figure 38–12).

During grasping, hand muscles must exert gripping forces perpendicular to the surface of the object to secure it between the fingers without slippage and to overcome the load forces imposed by gravity. Many neurons in the primary motor cortex are very sensitive to sensory feedback from somatic receptors in the hand that signal deformations of the skin perpendicular to the skin's surface. These cells are ideally organized to provide feedback control of grip and load forces during grasping and manipulation of an object.

In summary, when you look at your cup of coffee, neurons in the inferior parietal cortex, especially in the anterior intraparietal area, begin signaling the cup's affordances. These affordances are linked with specific grip representations in the parietal cortex and in the ventral premotor cortex. This activity is not sufficient to initiate grasping. Other areas controlling the initiation of action must also become active to allow the action represented in area F5 to be executed. When this occurs F5 neurons activate primary motor cortex neurons that control independent finger movements

Α

R

Figure 38–12 Neurons that control the movement of individual fingers are distributed throughout the hand-control area of the primary motor cortex. (Reproduced, with permission, from Schieber and Hibbard 1993.)

A. A view of the frontal pole of the monkey's cerebral cortex shows the interhemispheric fissure and lateral convexity. The colored spheres represent the locations of single neurons in the hand-control region of the primary motor cortex from which recordings were made.

B. The same data at a higher magnification. Neurons that discharge preferentially during isolated movements of individual digits and the wrist are represented by different colors. As shown by the scale at the left, the diameter of a sphere indicates a neuron's change in firing frequency (spikes per second). Neurons that are most active for a particular digit or for the wrist are not grouped together but instead are distributed throughout the hand-control area of the primary motor cortex.

and spinal motor neurons and interneurons involved in hand opening and closing. Finally, as your hand touches the cup's handle, sensory feedback provides the somatosensory information necessary for forming and maintaining a stable grip. This picture of grip generation is very schematic. It does not take into consideration the activity of reciprocal connections from the primary motor cortex to premotor areas and from there to the associated parietal areas. Even more important, we have focused exclusively on the cortical mechanisms responsible for action generation, leaving aside the important contributions of the cerebellum and basal ganglia (see Chapters 42 and 43).

The Supplementary Motor Complex Plays a Crucial Role in Selecting and Executing Appropriate Voluntary Actions

Classical electrical-stimulation studies of motor regions of the cortex showed that the medial wall of the frontal cortex contains a map of contralateral body movements (see Chapter 37). This region was initially called the supplementary motor area. Today there is agreement that this region contains two areas that have distinct cytoarchitectonic characteristics, connections, and functional properties: a more caudal supplementary motor area (SMA) proper and a more rostral presupplementary motor area (pre-SMA), which we will collectively call the supplementary motor complex (SMC).

The motor map in SMA covers the entire contralateral body but is not as detailed as the motor map in the primary motor cortex. Neurons in SMA require strong stimulus currents to evoke movements, which are often complex actions such as postural adjustments or stepping and climbing and can involve both sides of the body. Such movements are rarely evoked by stimulation of the primary motor cortex. In humans stimulation of the SMC below the threshold for movement initiation sometimes evokes an urge to move. Lesions of the SMC do not result in paralysis but do produce problems initiating or suppressing movement (Box 38–2).

The results of stimulation and lesion studies of the SMC indicate that motor centers outside of the primary motor cortex have a role in motor control. Further support for this idea emerged from studies of humans using evoked potentials. Recordings of slow cortical potentials from motor areas during the execution of self-generated movements showed that a slow potential arises in the frontal cortex 0.8 s to 1.0 s before the onset of movement. This signal, named the *readiness potential*, has its peak in the medial part of the precentral motor region over the SMC. Because it occurs well before movement, the readiness potential provides evidence that this region is involved in forming the intention to move, not just in movement execution.

Neurons in both the SMA and pre-SMA discharge before and during voluntary movements. There is a gradient in response properties across each area. Recent studies have indicated that much of the higherorder control of motor behavior originally attributed to SMA proper actually reflects the contribution of the

Box 38-2 Neurological Disorders Affect the Initiation and Suppression of Voluntary Behavior

Lesions of the supplementary motor area, presupplementary motor area, and prefrontal areas connected with them produce deficiencies in the initiation and release of movements.

Initiation deficits manifest themselves as loss of self-initiated arm movements, even though the patient can move when adequately prompted. This deficit can involve contralesional parts of the body (*akinesia*) and speech (*mutism*).

Release phenomena, in contrast, include a large variety of behaviors that patients cannot suppress when inappropriate. These include compulsive grasping of a stimulus when the hand touches it (forced grasping), irrepressible reaching and searching movements aimed at an object that has been presented visually (groping movement), and impulsive arm and hand movements to

grab nearby objects and even people without conscious awareness of the intention to do so (alien- or anarchichand syndromes).

Particularly interesting is the syndrome known as *utilization behavior*, in which a patient compulsively grabs objects and uses them without consideration of need or the social situation. Examples are picking up and putting on multiple pairs of glasses or reaching for and eating food even when the individual is not hungry or when the food is clearly part of someone else's meal.

These deficits in the initiation and suppression of actions may represent opposite facets of the same functional role for the supplementary motor area and especially the presupplementary motor area in the conditional control of voluntary behavior. pre-SMA. Unlike neurons in the primary motor cortex, the activity of most SMA neurons is less tightly coupled to particular actions of a specific part of the body and instead appears to be associated with more complex, coordinated motor acts of the hand, arm, head, or trunk.

In contrast, pre-SMA neurons often begin to discharge long before movement onset, are less tightly coupled to the execution of movements, and show an even more context-dependent relation to impending movements. For example, when tested in the same conditions used to study reach- and grasp-related activity in the parietal and ventral premotor cortex, the activity of pre-SMA neurons is less coupled to distinct actions of the hand or arm than neurons in the other regions, but is instead related to the overall act of reaching to grasp and manipulate objects.

Some pre-SMA neurons begin to discharge when a graspable object appears anywhere in the monkey's field of view and increase firing as the object moves within reach. Others are initially inhibited when the object appears but begin to discharge as soon as it moves within reach. Some neurons discharge during the actual reach-to-grasp movement, whereas others are inhibited. Although the patterns of response may vary, what remains constant is that changes in firing rate depend on whether an object can or cannot be acted upon. The pre-SMA may therefore contain a system that controls the execution of motor acts that are encoded in more lateral parietal-precentral circuits.

Many different roles in voluntary behavior have been attributed to the SMC, and its contribution remains controversial. One popular hypothesis was that the SMC is concerned with self-generated or internally guided behavior, whereas the dorsal and ventral premotor cortex primarily controls externally guided behavior. However, recent single-neuron studies do not support that functional dichotomy.

The SMC has been implicated in the organization and execution of movement sequences. Tanji and coworkers showed that some SMC neurons discharge before the performance of a particular sequence of three movements but not before a different sequence of the same movements (Figure 38–13). Other neurons discharge when a particular movement occurs in a specific position in a sequence or when a particular pair of consecutive movements occurs regardless of their order. Some SMC neurons encode the position of a movement in a sequence independently of the nature of the act or of how many movements remain to be executed before a reward is delivered.

Still other studies have suggested that the SMC is primarily concerned with the acquisition of certain

motor skills and less with their performance. Finally, the SMC has been implicated in the so-called *executive control* of behavior, such as the operations that are required to switch between different actions, plans, and strategies. For example, some SMC neurons discharge strongly when a subject receives a sensory cue instructing it to change movement targets or to suppress a previously intended movement.

These seemingly disparate behaviors may reflect a more general role of the SMC in *contextual control* of voluntary behavior. Contextual control is concerned with selecting and executing actions deemed appropriate on the basis of different combinations of internal and external cues as well as withholding inappropriate actions. Such control also situates a particular action in a goal-directed sequence or in a specific environmental and social context.

The Cortical Motor System Is Involved in Planning Action

So far we have focused on the role of cortical motor areas in the sensorimotor transformations required to reach for and grasp an object. However, voluntary behavior is not always directed specifically at objects or shaped by their physical properties. It is often determined by long-term goals and social conventions and may involve choosing from among alternative actions.

Furthermore, like the supplementary motor complex, many cortical areas implicated in the sensorimotor control of reaching and grasping also contribute to the choice of action. Neurons in these areas are involved not only in choosing particular actions but even in setting and applying the rules on which those choices are based.

Cortical Motor Areas Apply the Rules That Govern Behavior

Behavior is often guided by rules that link specific symbolic cues to particular actions. When driving your car you must perform different actions depending on whether a traffic light is green, yellow, or red. In monkeys that have learned to associate arbitrary cues with specific movements, many cells in the motor and premotor cortices respond selectively to specific cues.

This activity is dependent on the nature of the selection rule. In monkeys that have been trained to choose between several possible movements based on a spatial rule (an icon's location) or a semantic rule (an icon's designated meaning), many neurons in

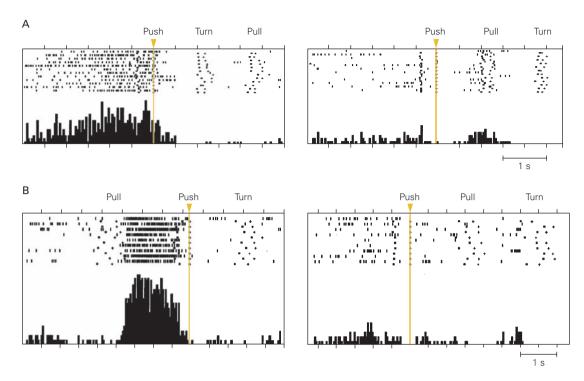

Figure 38–13 Some neurons in the supplementary motor complex encode a specific sequence of motor acts. (Modified, with permission, from Tanji 2001.)

A. A neuron discharges selectively during the waiting period before the first movement of the memorized sequence pushturn-pull (left panel). The cell remains relatively silent, however, when the sequence is push-pull-turn (right panel), even though the first movement in both sequences is the same. Triangles

at the top of each raster plot indicate the start of the first movement.

B. Records of a neuron whose activity increases selectively during the interval between completion of one motor act, a pull, and the initiation of another act, a push. The cell is not active when a push is the first movement in the sequence, or when pull is followed by turn.

both prefrontal and premotor cortices are more active when the animal chooses a movement using one rule but not the other. This strong correlation of neuronal responses with the selection rule shows that both prefrontal and premotor cortices use concrete rules to interpret behaviorally salient sensory inputs and associate them with appropriate actions. Such neuronal activity is related not to the identity of the sensory input or the chosen action but to the association between them.

Cortical motor areas are involved in the implementation of even very abstract rules. Jonathan Wallis and Earl Miller trained monkeys to decide whether to make a particular hand movement (a *go/no-go decision*). In each trial the monkey first had to make a perceptual decision whether the two images were the same or different. In some trials the animal was required to move its hand if the images were identical and to refrain from movement if they differed; in other trials the rule

was reversed (a *match/nonmatch decision*) after viewing sequential pairs of complex images. The animal therefore had to make two decisions, one perceptual and the other behavioral, neither of which had any a priori significance.

Neural populations in both the prefrontal and dorsal premotor cortices generated activity that correlated with either the perceptual or the behavioral decision (Figure 38–14). Neuronal correlates of the perceptual decision were more prominent in the prefrontal cortex, whereas correlates of the behavioral decision were stronger in the dorsal premotor cortex. Most strikingly, however, activity correlated with the perceptual choice was stronger and occurred earlier in the dorsal premotor cortex than in the prefrontal cortex. These results suggest that the dorsal premotor cortex has a major role in applying rules that govern the appropriateness of a behavior and in making decisions about movement according to the prevailing rules.

A Delayed match-to-sample task Rule for Test image 1 Delay Test image 2 Sample image Delay release Match Nonmatch Match (hold) (release) Nonmatch rule Nonmatch (release) Nonmatch rule Match Nonmatch (release) Match rule

Figure 38–14 Premotor cortex neurons choose particular voluntary behaviors based on decisional rules. (Reproduced, with permission, from Wallis and Miller 2003.)

Match (release)

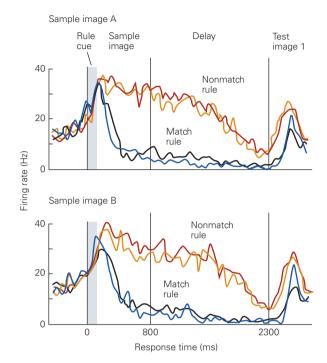

A. A monkey must make a decision about whether to release a lever or keep holding it based on two prior decisions: a perceptual choice, whether a test image is the same as or different from a sample image presented earlier, and a behavioral choice, whether the current rule is to release the lever when the test image is the same as the sample (match rule) or when it is different (nonmatch rule). The monkey is informed of the behavioral rule that applies in each trial by a rule cue, such as an auditory tone or juice drops, which is presented for 100 ms at the same time as the onset of the sample image.

The Premotor Cortex Contributes to Perceptual Decisions That Guide Motor Behavior

An elegant series of studies by Ranulfo Romo and his colleagues provides further evidence that cortical motor areas contain not only representations of the sensory information that guides voluntary movements but also the neuronal operations necessary to act on perceptual decisions. Although intuitively it may seem that perceptual processes are completely outside the domain of motor control, Romo's results indicate otherwise.

A monkey was trained to discriminate the difference in frequency between two brief vibratory stimuli applied to one finger and separated in time by a few

B Premotor neurons show rule-dependent activity

B. A neuron in the dorsal premotor cortex has a higher discharge rate whenever the nonmatch rule is in effect during the delay between the presentation of the first and second images. The top and bottom sets of responses were recorded from the same cell in trials with different sample images, indicating that the rule-dependent activity is not altered by changing the images. Nor, as shown by the pairs of differently colored histograms associated with each rule, does activity depend on the type of rule cue (auditory tone or juice drops). Other dorsal premotor cortex cells (not shown) respond preferentially to the match rule over the nonmatch rule. The differential activity of the neuron up to presentation of the test image reflects the nature of the rule that will guide the animal's motor response to the test image, not the physical nature of the visual stimuli or the motor response.

seconds. The animal had to decide whether the frequency of the second stimulus was higher or lower than the first and to report the perceptual decision by making one of two movements with the other hand.

The decision-making process in this task can be conceived as a chain of neural operations: encode the first stimulus frequency (f1) when it is presented; maintain a representation of f1 in working memory during the interval between the two stimuli; encode the second stimulus frequency (f2) when it is presented; compare f2 to the memory trace of f1; decide whether the frequency of f2 is higher or lower than that of f1; and, finally, use that decision to choose the appropriate movement of the other hand. Everything prior to

the last step would appear to fall entirely within the domain of sensory processing.

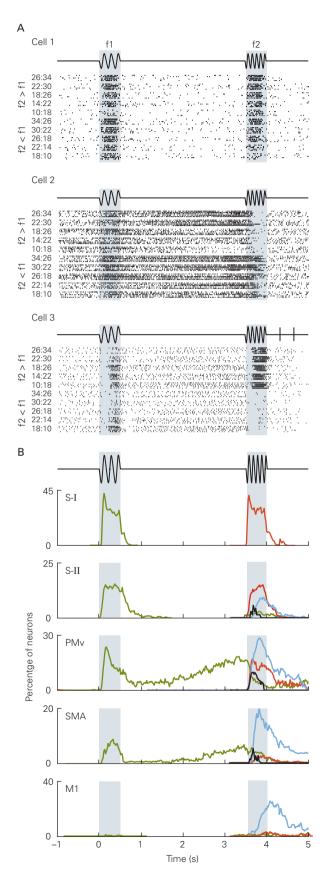

While the monkeys performed the task, neurons in the primary (S-I) and secondary (S-II) somatosensory cortices encoded the frequencies of the stimuli as they were presented. During the interval between f1 and f2 there was no sustained activity in S-I representing the memorized f1 and only a transient representation in S-II that vanished before f2 was presented.

Strikingly, however, many neurons in the prefrontal cortex, supplementary motor complex, and ventral premotor cortex encoded the f1 and f2 frequencies. Furthermore, some of the prefrontal and premotor neurons that encoded the frequency of f1 sustained their activity during the delay period between f1 and f2 (Figure 38–15). Most remarkably, many neurons in those areas, especially the ventral premotor cortex, encoded the *difference* in frequency between f2 and f1 independently of their actual frequencies. This centrally generated signal is appropriate to mediate the perceptual discrimination that determined the corresponding motor response. Neurons that encoded the f2–f1 difference were absent in S-I and were far more common in the supplementary motor complex and ventral premotor cortex than in S-II.

Figure 38–15 The ventral premotor cortex contains the operations required to choose a motor response based on sensory information. (Modified, with permission, from Romo, Hernandez, and Zainos 2004.)

A. These records of three neurons in the ventral premotor cortex of a monkey were made while the animal performed a task in which it had to decide whether the second of two vibration stimuli (f1 and f2, applied to the index finger of one hand) was of higher or lower frequency than the first. The choice was signaled by pushing one of two buttons with the nonstimulated hand. The frequencies of f1 and f2 are indicated by the numbers on the left of each set of raster plots. Cell 1 encoded the frequencies of both f1 and f2 while the stimuli were being presented but was not active at any other time. This response profile resembles that of many neurons in the primary somatosensory cortex. Cell 2 encoded the frequency of f1 and sustained its response during the delay period. During the presentation of f2 the neuron's response was enhanced when f1 exceeded f2 and suppressed when f2 exceeded f1. Cell 3 responded to f1 during stimulation and was weakly active during the delay period. However, during exposure to f2 the cell's activity explicitly signaled the difference f2-f1 independently of the specific frequencies f1 and f2.

B. The histograms show the percentage of neurons in different cortical areas whose activity correlated at each instant with different parameters during the tactile discrimination task. Green shows the correlation with f1, red the correlation with f2, black the interaction between f1and f2, and blue the correlation with the difference between f2-f1. (S-I, primary somatosensory cortex; S-II, secondary somatosensory cortex; PMv, ventral premotor cortex; SMA, supplementary motor area; M1, primary motor cortex.)

The premotor cortex activity that encodes, stores, and compares f1 and f2 does not necessarily contribute to the sensations evoked by the tactile stimuli. Nevertheless, these experiments show dramatically that premotor cortex contains prominent representations of selected sensory information and the neuronal operations required to make a perceptual decision prior to choosing a motor action.

The Premotor Cortex Is Involved in Learning Motor Skills

The premotor cortex has been implicated in the acquisition of new motor skills. Steven Wise and his colleagues recorded from neurons in the dorsal premotor cortex of a monkey while the animal learned a rule for associating unfamiliar visual cues with different directions of movement. Although an experienced monkey's choices were initially random, the animal could learn the rules within a few dozen trials.

Even though the monkey made an arm movement in response to each cue, many dorsal premotor neurons were only weakly active during the early, guessing phase of learning. Their activity gradually increased as the animal learned which cue signaled which movement. Other neurons showed a reciprocal decline in activity as the rules were acquired. These changes in activity reflected not only the movement choices but also the knowledge of the rule linking cues with actions.

These findings demonstrate that different cortical areas are involved in the acquisition of new motor skills and the recall of well-practiced skills. The role of cortical areas can change as new skills become motor habits that presumably require less attention, monitoring of performance, and feedback control.

Cortical Motor Areas Contribute to Understanding the Observed Actions of Others

Premotor and parietal areas may be active when no overt action is intended, such as when an individual is asked to imagine performing a certain motor act or when he observes someone else performing an action.

The first condition, termed *motor imagery*, has been demonstrated in humans by functional brain imaging. When an individual follows the instruction "imagine yourself performing a specific action," the premotor and parietal cortex and even the primary motor cortices become active even though no overt act occurs. If the instruction is "imagine observing yourself performing an action as in a picture and not as an acting

individual," the motor system is only weakly activated and activation of visual centers prevails. Motor imagery is interpreted by the brain as preparation to act disassociated from motor execution.

The second condition in which cortical motor circuits are activated is when an individual observes another individual performing motor acts that belong to his own motor repertory. The control of behavior and social interaction depends greatly on the ability to recognize and understand what others are doing and why they are doing it. Such understanding could of course come from visual analysis of the stimuli and subsequent inferential reasoning. An alternative interpretation of actions done by others is the direct matching hypothesis, according to which observation of the actions of others activates the motor circuits responsible for similar motor actions by the observer. This empathetic activation of motor circuits would provide a link between the observed actions and the observer's stored knowledge of the nature, motives, and consequences of his own corresponding actions.

Compelling evidence in support of the direct-matching hypothesis was provided when Rizzolatti and colleagues discovered a remarkable population of neurons in area F5 of the ventral premotor cortex. These so-called *mirror neurons* discharge both when the monkey performs a motor act and when it observes a similar act performed by another monkey or by the experimenter (Figure 38–16).

Mirror neurons do not respond when a monkey simply observes an object or when it observes mimed arm and hand actions without a target object. Because each of us understands the causes and outcomes of our own motor acts, the direct-matching hypothesis proposes that the activity of mirror neurons during observation of the actions of others provides a mechanism of transforming complex visual inputs into a high-level understanding of the observed actions.

Other experiments with monkeys have provided further evidence that mirror neurons become active whenever an individual recognizes and understands the motor acts of others. For example, a noisy action such as ripping paper or cracking open a peanut can be recognized from its sound without direct visual observation. Many area F5 mirror neurons respond to such sounds in the absence of visual input. Some F5 neurons selectively discharge when the monkey observes the act of grasping an object with the hand. When the target object is obscured by a screen, some of those mirror neurons discharge as the hand approaches the hidden object and continue to respond while the hand is behind the screen. If the monkey is first shown that there is no object behind the screen, however, those same neurons remain silent when the hand disappears

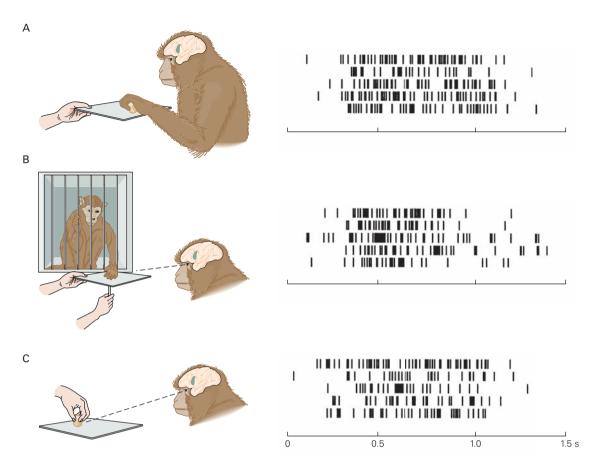

Figure 38–16 A mirror neuron in the ventral premotor cortex (area F5). (Reproduced, with permission, from Rizzolatti et al. 1996.)

A. The neuron is active when the monkey grasps an object.

- **B.** The same neuron is also excited when the monkey observes another monkey grasping the object.
- **C.** The neuron is similarly activated when the monkey observes the human experimenter grasping the object.

behind the screen. This result suggests that mirror neurons generate an internal representation of the action even when it is not visible.

Although area F5 receives no direct input from visual areas, the rostral intraparietal cortex that projects to it receives visual input from the superior temporal sulcus, a region that encodes high-level visual information but is devoid of motor signals. Some neurons in the rostral intraparietal lobule have properties similar to F5 mirror neurons. They discharge more strongly when the monkey observes motor acts that have a particular goal, for example grasping food to eat it but not simply to move it (Figure 38–17). This type of coding indicates that when the monkey understands the intention behind an observed action, it is able to predict the next motor action.

Neurophysiological and brain-imaging studies show that humans too are endowed with the mirror mechanism, matching observed actions with actions encoded in their motor system. This mechanism is located in various areas including the rostral inferior parietal lobule, intraparietal sulcus, ventral premotor cortex, and the posterior sector of the inferior frontal gyrus. Recent studies suggest that defects in the human mirror-neuron system contribute to some of the symptoms of autism. Whereas the motor system of a normally developing child is activated when he observes another person performing an action, this activation is lacking in children with autism. As a result, autistic children may lack the neuronal mechanism that normally mediates direct, experiential understanding of the intentions of others. Autistic children who are able to understand the behavior of others are thought to use cognitive inferential processes to compensate for the lack of a functional mirrorneuron system.

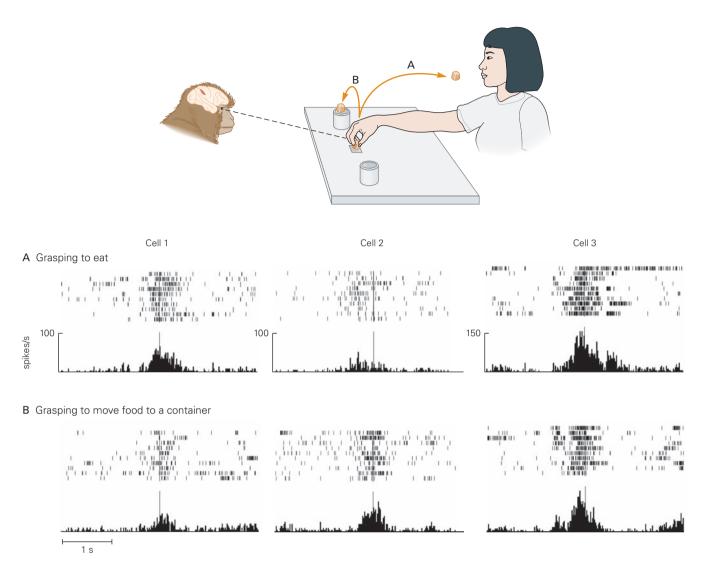

Figure 38–17 Mirror neurons in the inferior parietal cortex of a monkey are activated when the monkey observes a motor act. A monkey observes the experimenter perform the same grasping action to bring food to the mouth (A) or to place it into a container (B). Cell 1 discharges more strongly when the monkey observes the experimenter grasp the food to eat it,

whereas cell 2 discharges more briskly when the monkey observes the experimenter grasp the food to put it into another container. Cell 3 shows no difference in activity between the two conditions. Raster plots and histograms are aligned with the instant when the experimenter touches the food to be grasped. (Modified, with permission, from Fogassi et al. 2005.)

The involvement of cortical motor circuits in understanding and predicting the outcomes of observed events may not be limited to the mirror-neuron mechanism in the parietal and ventral premotor cortex. Recent experiments have revealed similar processes in the dorsal premotor cortex. Cisek and Kalaska found many neurons in the dorsal premotor cortex that showed directionally tuned activity when a monkey used visual cues to select the correct target for arm and cursor movements from among eight possibilities. The animal watched the cues and cursor motions

on a monitor; the cursor was moved by an unseen party. The monkey received a juice reward when the cursor approached the correct target but not if the cursor moved in the wrong direction. The monkey began to lick the reward tube shortly after the cursor started to move in the correct direction but long before the juice was actually delivered. When the cursor moved in the wrong direction, however, the monkey quickly removed its mouth from the tube. This behavior showed that the monkey correctly interpreted what it saw and predicted the consequences.

Remarkably, activity in the majority of dorsal premotor neurons was strikingly similar whether the monkey used visual cues to plan and make arm movements or simply observed and predicted the outcome. Those neurons stopped responding during observation if no reward was delivered after correct trials or if the animal became sated and was no longer interested in receiving rewards. This showed that the neurons were not simply responding to the sensory inputs, but instead were processing the observed sensory events to predict their ultimate outcome for the subject, namely the likelihood of a free reward.

The Relationship between Motor Acts, the Sense of Volition, and Free Will Is Uncertain

At the beginning of the previous chapter we stated that voluntary behavior is willful: An action is considered voluntary if it is intentionally initiated by the actor following a decision to act, including a rejection of the alternative of doing nothing. This concept is a fundamental tenet of our legal system: A person is subject to criminal prosecution or civil liability for his actions if he performs them voluntarily and with full knowledge of their implications.

The subjective experience associated with a voluntary movement is different from that evoked when the movement is passively imposed; it includes a sense of ownership of the action. Our everyday experience also leaves us with the sense that our voluntary behavior is under conscious control and that intention precedes action. However, many skilled voluntary movements can be performed with minimal levels of conscious attention; we can, for example, ride a bicycle or drive a car while simultaneously engaged in conversation.

The relationship between behavior, intention, sense of volition, and free will has long been the subject of intense debate in philosophy and psychology. Some investigators propose that, contrary to our everyday impression, our subjective experience that intention and volition are mental processes that precede action is in fact a post hoc construct of the brain. According to this hypothesis, whenever the brain detects a temporal correlation between a motor command and subsequent sensory events, including feedback from the moving limb, it retrospectively infers that the motor command caused those events and therefore that the action was intended and that the individual was the causal agent.

Benjamin Libet and his colleagues explored this issue in the early 1980s by examining electroencephalographic activity during a self-paced movement task. They asked subjects to make a hand movement at a

time of their choosing and then to use a clock-like visual time scale to report when they first became aware of his or her intention to move. Their surprising finding was that the subjects reported that they first recognized the intention to move only about 200 ms before the onset of muscle activity, as much as a second after the onset of the readiness potential, a bilateral signal arising in the frontal cortex and associated with the volitional preparation for movement. Libet concluded that neural processes leading to the initiation of a voluntary movement begin long before the subject reports any awareness of the intention to move and thus that consciousness and free will have little role in the early processes related to the control of voluntary behavior.

Libet's findings have been corroborated by other studies that show that the timing of the awareness of intention is better correlated with the onset of a later electroencephalographic event, the *lateralized readiness potential*, recorded over the motor cortex contralateral to the active limb about 200 ms before movement. The lateralized readiness potential is generally assumed to reflect the end of the decision making process and the onset of the formation of the motor command in the motor cortex.

Although the issue remains controversial, the consensus from these studies is that conscious awareness that one is about to perform a voluntary action is temporally coupled to neural activity in the brain areas associated with the planning and control of the movements. The sense that one is the causal agent of an impending action and that the action is an act of free will may be linked to neural activity in movement-related areas of the brain, rather than activity in separate, higher-order cortical areas that supposedly instruct motor areas what to do.

An Overall View

Not long ago the motor system was viewed as a passive apparatus used by more "intelligent" parts of the brain to implement their plans. Experimental results in recent years have required a profound reevaluation of the role of the motor system in the totality of brain function.

Theoretical and behavioral investigations suggest that the control of motor behavior involves a sequence of neuronal operations that select, plan, and execute a movement. Neurophysiological studies identify those operations in populations of neurons in the parietal, premotor, prefrontal, and primary motor regions of the cerebral cortex. Neurons do not encode motor acts in terms of conventional coordinate systems and motor parameters derived from first principles of physics and engineering. Instead their activity reflects empirical solutions shaped by evolution.

Functions are distributed throughout the cortical motor system without a fixed serial order. A given neuronal operation is spread across multiple cortical areas and related operations occur in parallel in several areas. The particular distribution of activity across this network varies from moment to moment as a function of changing combinations of information and neuronal operations required to learn, plan, and execute the desired behavior in different situations.

Perception, cognition, and action have traditionally been considered distinct and serially ordered functions: An individual perceives the world, reflects on the resultant internal image of the world, and finally acts. This perspective relegates the motor system to the role of a passive apparatus that implements the decisions made by cleverer parts of the brain. Contemporary research indicates that perception, cognition, and action are neither functionally independent nor anatomically segregated. Neural correlates of the decision-making operations involved in voluntary behavior are distributed across cortical areas responsible for the motor control of the effectors that implement those decisions. No single area is responsible for general decisions about action that are then relayed to appropriate output systems for execution.

The complex behavior of higher primates is often regarded as a consequence of the development of sophisticated and adaptive perceptual and cognitive systems. This point of view may invert the evolutionary relationship. The most sophisticated cognitive processes have no inherent survival value without the means to translate them into action. The evolution of increasingly complex motor interactions with the world may have provided the evolutionary driving force that led to the development of more sophisticated perceptual and cognitive capacities to serve the needs of action.

Smooth Pursuit Involves the Cerebral Cortex, Cerebellum, and Pons

Some Gaze Shifts Require Coordinated Head and Eye Movements

An Overall View

In this and the next two chapters we consider the motor systems concerned with gaze, balance, and posture. As we explore the world around us, these motor systems act to stabilize our body, particularly our eyes. In examining these motor systems we shall be concerned with how these systems have resolved three biological challenges to knowing where we are in space: How do we visually explore our environment quickly and efficiently? How do we compensate for planned and unplanned movements of the head? How do we stay upright?

The gaze system stabilizes the image of an object on the retina when the object moves in the world or the head moves and keeps the eyes still when the image remains stationary. It has two components: the oculomotor system and the head-movement system. The oculomotor system moves the eyes in the orbits; the head-movement system moves the eye sockets.

In this chapter we describe the oculomotor system and how visual information guides eye movements. It is one of the simplest motor systems, requiring the coordination of only the 12 muscles that move the two eyes. In humans and primates the main job of the oculomotor system is to control the position of the fovea, the central, most sensitive part of the retina. The fovea is less than 1 mm in diameter and covers a tiny fraction of the visual field. When we want to examine an object, we must move its image onto the fovea.

Six Neuronal Control Systems Keep the Eyes on Target

Hermann Helmholtz and other 19th-century psychophysicists who first studied visual perception systematically were particularly interested in eye movements. They appreciated that an analysis of eye movements was essential for understanding visual perception, but they did not realize that there is more than one kind of eye movement. In 1890 Edwin Landott discovered a second type of eye movement. When reading, the eyes do not move smoothly along a line of text but make fast, intermittent movements—saccades—each followed by a short pause (see Chapter 29).

By 1902 Raymond Dodge was able to outline five distinct types of eye movement that direct the fovea to a visual target and keep it there. All of these eye movements share an effector pathway originating in the three bilateral groups of oculomotor neurons in the brain stem.

- Saccadic eye movements shift the fovea rapidly to a new visual target.
- Smooth-pursuit movements keep the image of a moving target on the fovea.
- Vergence movements move the eyes in opposite directions so that the image is positioned on both foveage
- Vestibulo-ocular reflexes hold images still on the retina during brief head movements.
- Optokinetic movements hold images stationary during sustained head rotation or translation.

A sixth system, the fixation system, holds the eye stationary during intent gaze when the head is not moving. This requires active suppression of eye movement. The optokinetic and vestibular systems are discussed in Chapter 40; we consider the remaining four systems here.

An Active Fixation System Keeps the Fovea on a Stationary Target

Vision is most accurate when the eyes are still. The gaze system actively prevents the eyes from moving when we examine an object of interest. It is not as active in suppressing movement when we are doing something that does not require vision, such as mental arithmetic. Patients with disorders of the fixation system—for example, some individuals with congenital nystagmus—have poor vision not because their visual acuity is deficient but because they cannot hold their eyes still enough for the visual system to work correctly.

The Saccadic System Points the Fovea Toward Objects of Interest

Our eyes explore the world in a series of very quick saccades that move the fovea from one fixation point to another (Figure 39–1). Saccades allow us to scan the environment quickly and to read. They are highly stereotyped; they have a standard waveform with a single smooth increase and decrease of eye velocity. They are also extremely fast, occurring within a fraction of a second at angular speeds up to 900 degrees per second (Figure 39–2A). The velocity of a saccade is determined by only the distance of the target from the fovea. We can change the amplitude and direction of saccades voluntarily but not their speed.

Ordinarily there is no time for visual feedback to modify the course of a saccade; corrections to the direction of movement are made in successive saccades. Only fatigue, drugs, or pathological states can slow saccades. Accurate saccades can be made not only to visual targets but also to sounds, tactile stimuli, memories of locations in space, and even verbal commands ("look left").

The Smooth-Pursuit System Keeps Moving Targets on the Fovea

The smooth-pursuit system holds the image of a moving target on the fovea by calculating how fast the target is moving and moving the eyes at the same speed. Smooth-pursuit movements have a maximum angular velocity of approximately 100 degrees per second, much

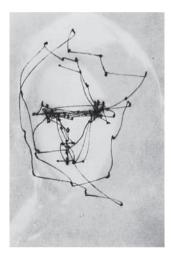

Figure 39–1 Eye movements track the outline of an object of attention. An observer looks at a picture of a woman for 1 minute. The resulting eye positions are then superimposed on the picture. As shown here, the observer concentrated on certain features of the face, lingering over the woman's eyes and mouth (*fixations*) and spending less time over intermediate positions. The rapid movements between fixation points are *saccades*. (Reproduced, with permission, from Yarbus 1967.)

slower than saccades. Drugs, fatigue, alcohol, and even distraction degrade the quality of these movements.

Smooth pursuit and saccades have very different central control systems. This is best seen when a target jumps away from the center of gaze and then slowly moves back toward it. A smooth-pursuit movement is initiated first because the smooth-pursuit system has a shorter latency and responds to target motion on the peripheral retina as well as on the fovea. As the target

moves back toward the center of gaze, the eye briefly moves away from the target before the saccade is initiated (Figure 39–2B). The subsequent saccade then brings the eye to the target.

The Vergence System Aligns the Eyes to Look at Targets at Different Depths

The smooth-pursuit and saccade systems produce conjugate eye movements: Both eyes move in the same direction and at the same speed. In contrast, the vergence system produces disconjugate movements of the eyes. When we look at an object that is close to us, our eyes rotate toward each other, or *converge*; when we look at an object that is farther away, they rotate away from each other, or *diverge* (Figure 39–3). These disconjugate movements ensure that the image of the object falls on the foveae of both retinas. Whereas the visual system uses slight differences in left and right retinal positions, or *retinal disparity*, to create a sense of depth, the vergence system drives disconjugate movements to eliminate retinal disparity at the fovea.

Vergence is a function of the horizontal rectus muscles only. Near-field viewing is accomplished by simultaneously increasing the tone of the medial recti muscles and decreasing the tone of the lateral recti muscles. Distance viewing is accomplished by reducing medial-rectus tone and increasing lateral-rectus tone. Accommodation and vergence are controlled by midbrain neurons in the region of the oculomotor nucleus. Neurons in this region discharge during vergence, accommodation, or both.

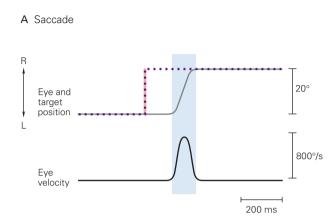

At any given time the entire visual field is not in focus on the retina. When we look at something close by, distant objects are blurred. When we look at something far away, near objects are blurred. When we wish to focus on an object in a closer plane in the visual field, the oculomotor system contracts the ciliary muscle, thereby changing the radius of curvature of the lens. This process is called *accommodation*. In older individuals accommodation declines owing to increased rigidity of the lens; reading glasses are then needed to focus images at short distances.

Accommodation and vergence are linked. Accommodation is elicited by the blurring of an image, and whenever accommodation occurs the eyes also converge. Conversely, retinal disparity induces vergence, and whenever the eyes converge, accommodation also takes place. At the same time, the pupils transiently constrict to increase the depth of field of the focus. The linked phenomena of accommodation, vergence, and pupillary constriction comprise the *near response*.

Eye positionTarget position

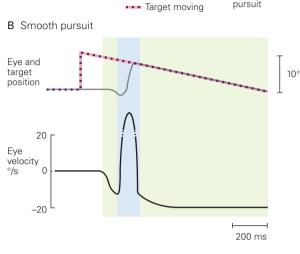

Saccade

Smooth-

A. The human saccade. At the beginning of the plot the eye is on the target (the traces representing eye and target positions are superimposed). Suddenly the target jumps to the right, and within 200 ms the eye moves to bring the target back to the fovea. Note the smooth, symmetric velocity profile. Because eye movements are rotations of the eye in the orbit, they are described by the angle of rotation. Similarly, objects in the visual field are described by the angle of arc they subtend at the eye. Viewed at arm's length, a thumb subtends an angle of approximately 1 degree. A saccade from one edge of the thumb to the other therefore traverses 1 degree of arc.

B. Human smooth pursuit. In this example the subject is asked to make a saccade to a target that jumps away from the center of gaze and then slowly moves back to center. The first movement seen in the position and velocity traces is a smooth-pursuit movement in the same direction as the target movement. The eye briefly moves *away* from the target before a saccade is initiated because the latency of the pursuit system is shorter than that of the saccade system. The smooth-pursuit system is activated by the target moving back toward the center of gaze, the saccade adjusts the eye's position to catch the target, and thereafter smooth pursuit keeps the eye on the target. The recording of saccade velocity is clipped so that the movement can be shown on the scale of the pursuit movement, an order of magnitude slower than the saccade.

The neural signal sent to each eye muscle has two components, one related to eye position and the other to eye velocity. Velocity and position signals are generated by different neural systems that converge on the motor neuron. In addition, horizontal and vertical eye movements are specified independently; vertical movements are generated in the mesencephalic reticular formation and horizontal movements in the pontine reticular formation.

Inhibitory neurons suppress unwanted eye movements. Omnipause neurons in the pontine reticular formation prevent excitatory neurons in the brain stem from stimulating the motor neurons. Fixation neurons in the rostral superior colliculus inhibit movement-related neurons in the colliculus while exciting omnipause neurons in the pons. Inhibitory neurons in the substantia nigra inhibit these same movement-related neurons from firing except during saccades.

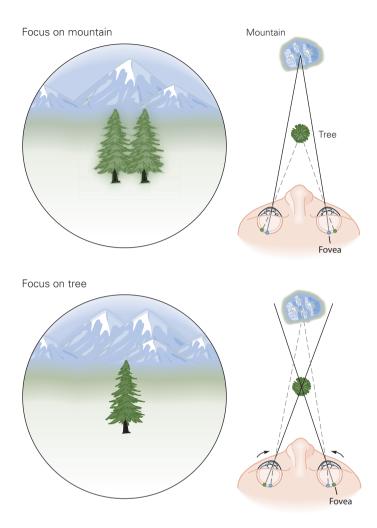

The Eye Is Moved by the Six Extraocular Muscles

Eye Movements Rotate the Eye in the Orbit

To a good approximation, the eye is a sphere that sits in a socket, the orbit. Eye movements are simply rotations of the eye in the orbit. The eye's orientation can be defined by three axes of rotation—horizontal, vertical, and torsional—that intersect at the center of the eyeball, and eye movements are described as rotations around these axes. Horizontal and vertical eye movements change the line of sight by redirecting the fovea; torsional eye movements rotate the eye around the line of sight but do not change gaze.

Horizontal rotation of the eye away from the nose is called *abduction* and rotation toward the nose is *adduction*. Vertical movements are referred to as *elevation*.

Figure 39–3 Vergence movements. When the eyes focus on a distant mountain, images of the mountain lie on the foveae, whereas those of the nearer tree occupy different retinal positions relative to the two foveae, yielding the percept of a double image. When the viewer looks instead at the tree (below), the vergence system must rotate each eye inward. Now the tree's image occupies similar positions on the foveae of both retinas and is seen as one object, but the mountain's images occupy different locations on the retinas and appear double. (Reproduced, with permission, from F. A. Miles.)

(upward rotation) and *depression* (downward rotation). Finally, torsional movements include *intorsion* (rotation of the top of the cornea toward the nose) and *extorsion* (rotation away from the nose).

Except for vergence, most eye movements are conjugate. For example, during gaze to the right the right eye abducts and the left eye adducts. Similarly, if the right eye extorts, the left eye intorts.

The Six Extraocular Muscles Form Three Agonist-Antagonist Pairs

Each eye is rotated by six extraocular muscles arranged in three agonist–antagonist pairs (Figure 39–4). The four rectus muscles (lateral, medial, superior, and inferior) share a common origin, the annulus of Zinn, at the apex of the orbit. They insert on the surface of the eye, or sclera, anterior to the eye's equator. The origin

of the inferior oblique muscle is on the medial wall of the orbit; the superior oblique muscle's tendon passes through the trochlea, or pulley, before inserting on the globe, so that its effective origin is also on the medial wall of the orbit. The oblique muscles insert on the posterior globe.

Each muscle has a dual insertion. The part of the muscle farthest from the eye inserts on a soft-tissue pulley through which the rest of the muscle passes on its way to the eye. When the extraocular muscles contract, they not only rotate the eye but also change their pulling directions.

The actions of the extraocular muscles are determined by their geometry and by the position of the eye in the orbit. The medial and lateral recti rotate the eye horizontally; the medial rectus adducts, whereas the lateral rectus abducts. The superior and inferior recti and the obliques rotate the eye both vertically and

torsionally. The superior rectus and inferior oblique elevate the eye, and the inferior rectus and superior oblique depress it. The superior rectus and superior oblique intort the eye, whereas the inferior rectus and inferior oblique extort it.

The relative amounts of vertical and torsional rotation produced by the superior and inferior recti and the obliques depend on eye position. The superior and inferior recti exert their maximal vertical action when the eye is abducted, that is, when the line of sight is parallel to the muscles' pulling directions. Conversely, the oblique muscles exert their maximal vertical action when the eye is adducted (Figure 39–5).

Movements of the Two Eyes Are Coordinated

Humans and other animals with eyes in front have binocular vision. This facilitates stereopsis, the ability to perceive a visual scene in three dimensions, as well as depth perception. At the same time, binocular vision requires precise coordination of the movements of the two eyes so that both foveae are always directed at the target of interest. For most eye movements both eyes must move by the same amount and in the same direction. This is accomplished, in large part, through the pairing of eye muscles in the two eyes.

Just as each eye muscle is paired with its antagonist in the same orbit (eg, the medial and lateral recti), it is also paired with the muscle that moves the opposite eye in the same direction. For example, coupling of the left lateral rectus and right medial rectus moves both eyes to the left during a leftward saccade. The orientations of the vertical muscles are such that each pair consists of one rectus muscle and one oblique muscle. For example, the left superior rectus and the right inferior oblique both move the eyes upward in left gaze. The binocular muscle pairs are listed in Table 39–1.

The Extraocular Muscles Are Controlled by Three Cranial Nerves

The extraocular muscles are innervated by groups of motor neurons whose cell bodies are clustered in three

A Lateral view

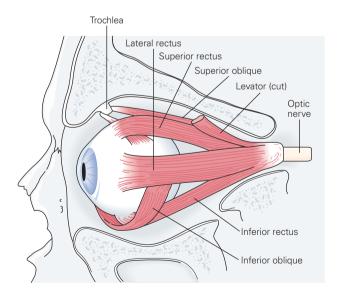

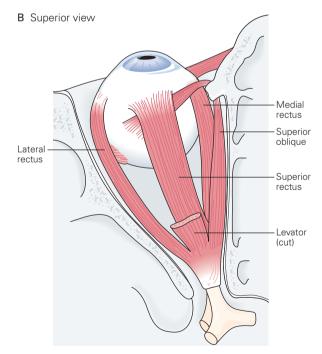

Figure 39–4 The origins and insertions of the extraocular muscles.

A. Lateral view of the left eye with the orbital wall cut away. Each rectus muscle inserts in front of the equator of the globe so that contraction rotates the cornea toward the muscle. Conversely, the oblique muscles insert behind the equator and contraction rotates the cornea away from the insertion.

The superior oblique muscle passes through a bony pulley, the trochlea, before it inserts on the globe. The levator muscle of the upper eyelid raises the lid.

B. Superior view of the left eye with the roof of the orbit and the levator muscle cut away. The superior rectus passes over the superior oblique and inserts in front of it on the globe.

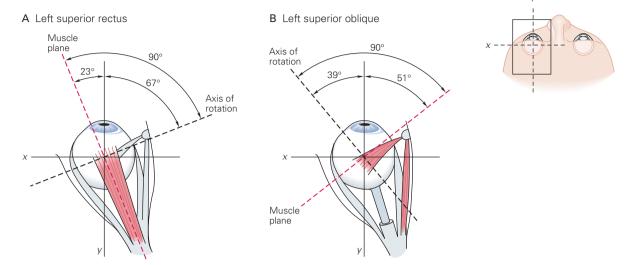

Figure 39–5 Each superior rectus and oblique muscle has both torsional and elevational actions. How much elevation and torsion each muscle provides depends on the position of the eye. (Adapted, with permission, from von Noorden 1980.)

A. When eye position is in the primary visual axis (the *y* axis in the diagram) or lateral to it (*abduction*), elevation is provided by the superior rectus and all of the intorsion is from the superior oblique muscle. When the eye is positioned completely medial to the visual axis (*adduction*), intorsion comes predominantly

from the superior rectus and most of the elevation comes from the inferior oblique.

B. When the eye is positioned 16 degrees or more laterally from the primary visual axis, the superior oblique intorts the eye and depression comes from the inferior rectus. When it is completely medial to the visual axis, the superior oblique rotates the eye vertically downward and all of the intorsion comes from the superior rectus.

nuclei in the brain stem (Figure 39–6). The lateral rectus is innervated by the abducens nerve (cranial nerve VI), whose nucleus lies in the pons in the floor of the fourth ventricle. The superior oblique muscle is innervated by the trochlear nerve (cranial nerve IV), whose nucleus is located in the midbrain at the level of the inferior colliculus. (The trochlear nerve gets its name from the trochlea, the bony pulley through which the superior oblique muscle travels.)

Figure 39–6 Vertical Muscle Action in Adduction and Abduction

Muscle	Action in adduction	Action in abduction
Superior rectus	Intorsion	Elevation
Inferior rectus	Extorsion	Depression
Superior oblique	Depression	Intorsion
Inferior oblique	Elevation	Extorsion

All the other extraocular muscles—the medial, inferior, and superior recti and the inferior oblique—are innervated by the oculomotor nerve (cranial nerve III), whose nucleus lies in the midbrain at the level of the superior colliculus. The oculomotor nerve also contains fibers that innervate the levator muscle of the upper eyelid. Cell bodies of axons innervating both eyelids are located in the central caudal nucleus, a single midline structure within the oculomotor complex. Finally, traveling with the oculomotor nerve are parasympathetic fibers that innervate the iris sphincter muscle, the constrictor of the pupil, and the ciliary muscles that adjust the curvature of the lens to focus the eye during accommodation.

The pupil and eyelid also have sympathetic innervation, which originates in the intermediolateral cell column of the ipsilateral upper thoracic spinal cord. Fibers of these neurons synapse on cells in the superior cervical ganglion in the upper neck. Axons of these postganglionic cells travel along the carotid artery to the carotid sinus and then into the orbit. Sympathetic pupillary fibers innervate the iris dilator muscle, causing the pupil to dilate and thus providing the pupillary component of the so-called "fight or flight" response.

Sympathetic fibers also innervate Müller's muscle, a secondary elevator of the upper eyelid. The sympathetic control of pupillary dilatation and lid elevation is responsible for the "wide-eyed" look of excitement and sympathetic overload.

The best way to understand the actions of the extraocular muscles is to consider the eye movements that remain after a lesion of a specific nerve (Box 39–1).

Extraocular Motor Neurons Encode Eye Position and Velocity

We can illustrate how the gaze system generates eye movements by considering the activity of an oculomotor neuron during a saccade. To move the eye quickly to a new position in the orbit and keep it there, two

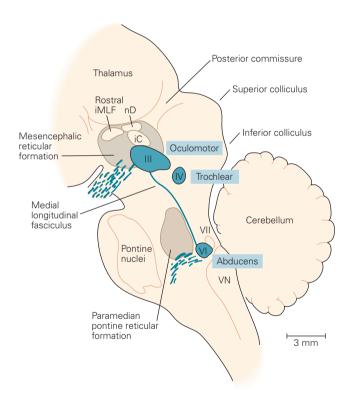

Figure 39–6 The ocular motor nuclei in the brain stem. The nuclei are shown in a parasagittal section through the thalamus, pons, midbrain, and cerebellum of a rhesus monkey. The oculomotor nucleus (cranial nerve III) lies in the midbrain at the level of the mesencephalic reticular formation. The trochlear nucleus (nerve IV) is slightly caudal, and the abducens nucleus (nerve VI) lies in the pons at the level of the paramedian pontine reticular formation, adjacent to the fasciculus of the facial nerve (VII). Compare Figure 45–5. (iC, interstitial nucleus of Cajal; iMLF, interstitial nucleus of the medial longitudinal fasciculus; nD, nucleus of Darkshevich; VN, vestibular nuclei.) (Adapted, with permission, from Henn et al. 1984.)

passive forces must be overcome: the elastic force of the orbit, which tends to restore the eye to a central position in the orbit, and a velocity-dependent viscous force that opposes rapid movement. Thus the motor signal must include information about tonic position, which opposes the elastic force, and velocity, which overcomes orbital viscosity and moves the eye quickly to a new position.

Information about the position and velocity of the eye is conveyed by the discharge frequency of an oculomotor neuron (Figure 39–8). The firing rate of the neuron rises rapidly as the eye's velocity increases from 0 degrees to 900 degrees per second; this is called the *saccadic pulse*. The frequency of this pulse determines the speed of the saccade, whereas the duration of the pulse controls the duration of the saccade. The difference in the firing rates before and after the saccade is called the *saccadic step*. As described below, the pulse and step are generated by different brain stem structures.

Oculomotor neurons differ from skeletal motor neurons in several ways. Although the extraocular muscles are rich in sensors resembling the muscle spindles of skeletal muscles, there are no ocular stretch reflexes. Oculomotor neurons do not have recurrent inhibitory connections. All oculomotor neurons participate equally in all types of eye movements; no motor neurons are specialized for saccades or smooth pursuit.

However, like skeletal motor units, eye motor units are recruited in a fixed sequence (see Chapter 38). Regardless of the type of eye movement, the specific ocular motor neurons recruited depend on the position of the eye in the orbit and the desired eye velocity. For example, as the eye moves laterally the number of active abducens neurons increases, causing more muscle fibers in the lateral rectus to contract.

The Motor Circuits for Saccades Lie in the Brain Stem

How are the motor signals for velocity and position of the eye determined? The higher centers that control gaze specify only a desired change in eye position. The activity of neurons in these centers specifies a target location in the visual field. This location signal must be transformed into a motor signal that encodes the velocity and position of eye movement.

Horizontal Saccades Are Generated in the Pontine Reticular Formation

The signal for horizontal saccades originates in the paramedian pontine reticular formation, adjacent to the

Box 39–1 Extraocular Muscle or Nerve Lesions

Patients with lesions of the extraocular muscles or their nerves complain of double vision (diplopia) because the images of the object of gaze no longer fall on the corresponding retinal locations in both eyes. Lesions of each nerve produce characteristic symptoms that depend on which extraocular muscles are affected. In general, double vision increases when the patient tries to look in the direction of the weak muscle.

Abducens Nerve

A lesion of the abducens nerve (VI) causes weakness of the lateral rectus. When the lesion is complete the eye cannot abduct beyond the midline, such that a horizontal diplopia increases when the subject looks in the direction of the affected eye.

Trochlear Nerve

A lesion of the trochlear nerve (IV) affects both torsional and vertical eye movements. When the patient looks straight ahead, the affected eye is above the normal eye (Figure 39–7A). The difference increases when the patient looks to the right, adducting the eye with the weak muscle (Figure 39–7B left), and decreases when the patient looks to the left, abducting the eye (Figure 39–7B right), because the superior oblique predominantly depresses the eye in adduction.

The deficit is worse when patients attempt to depress and adduct the eye, but improves when they elevate the adducted eye (Figure 39–7C). Patients with superior oblique paresis often keep their heads tilted away from the affected eye. A tilt of the head to one side, such that one ear is pointed downward, induces a small torsion of the eye in the opposite direction, known as ocular counter-roll.

When the head tilts to the left, the left eye is ordinarily intorted by the left superior rectus and left superior oblique, while the right eye is extorted by the right superior rectus and right inferior oblique. The elevation action of the superior rectus is canceled by the depression action of the superior oblique, so the eye only rotates. When the head tilts to the right, the inferior

oblique and inferior rectus extort the left eye and the superior oblique relaxes.

With paresis of the left superior oblique, when the head tilts to the left the elevation of the superior rectus is unopposed and the eye moves upward (Figure 39–7D right). The diplopia can be minimized by tilting the head to the right (Figure 39–7D left).

Oculomotor Nerve

A lesion of the oculomotor nerve (III) has complex effects because this nerve innervates multiple muscles. A complete lesion spares only the lateral rectus and superior oblique muscles. Thus the paretic eye is typically deviated downward and abducted at rest, and it cannot move medially or upward from a middle position. Downward movement is partially affected because the inferior rectus muscle is weak but the superior oblique is preserved.

Because the fibers that control lid elevation, accommodation, and pupillary constriction travel in the oculomotor nerve, damage to this nerve also results in drooping of the eyelid (ptosis), blurred vision for near objects, and pupillary dilation (mydriasis). Although sympathetic innervation is still intact with an oculomotor nerve lesion, the ptosis is essentially complete, since Müller's muscle contributes less to elevation of the upper eyelid than does the levator muscle of the upper eyelid.

Sympathetic Oculomotor Nerves

Sympathetic fibers innervating the eye arise from the thoracic spinal cord, traverse the apex of the lung, and ascend to the eye on the outside of the carotid artery.

Interruption of the sympathetic pathways to the eye yields Horner syndrome, whose characteristic features are a partial ipsilateral ptosis owing to weakness of Müller's muscle and a relative constriction (miosis) of the ipsilateral pupil. The pupillary asymmetry is most pronounced in low light because the normal pupil is able to dilate but the pupil affected by Horner syndrome is not.

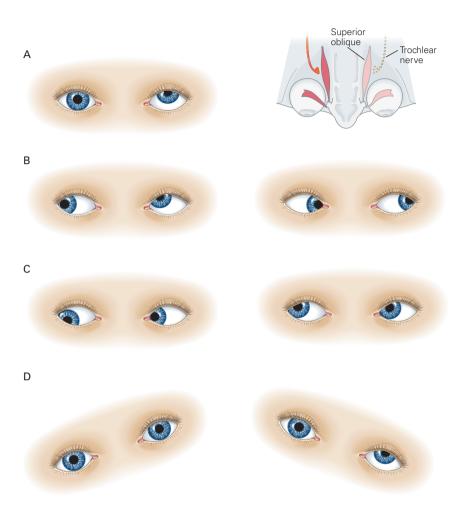

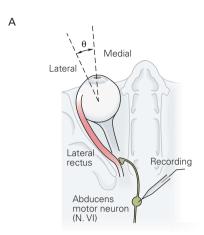

Figure 39–7 Effect of a left trochlear nerve palsy. The trochlear nerve innervates the superior oblique muscle, which inserts behind the equator of the eye. It depresses the eye when it is adducted and intorts the eye when it is abducted.

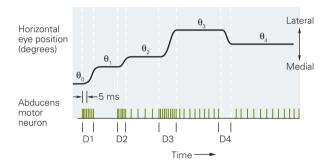

- A. Hypertropia occurs when the eye is in the center of the orbit and the left eye is slightly above the right eye.
- **B.** The hypertropia is worse when the eye is adducted because the unopposed inferior oblique pushes the eye higher (left). The condition is improved when the eye is abducted (right) because the superior oblique contributes less to depression than to intorsion.
- C. When the patient looks to the right the hypertropia is worse on downward gaze (left) than it is on upward gaze (right).
- D. The hypertropia is improved by head tilt to the right (left) and worsened by tilt to the left (right). The ocular counterrolling reflex induces intorsion of the left eye on leftward head tilt, and extorsion of the eye on rightward head tilt (see Chapter 40). With leftward head tilt, intorsion requires increased activity of the superior rectus, whose elevating activity is unopposed by the weak superior oblique, causing increased hypertropia. With rightward head tilt and extorsion of the left eye, the unopposed superior rectus muscle is less active, and the hypertropia decreases.

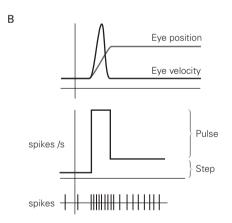

Figure 39–8 Oculomotor neurons signal eye position and velocity.

A. The record is from an abducens neuron of a monkey. When the eye is positioned in the medial side of the orbit the cell is silent (position θ_0). As the monkey makes a lateral saccade there is a burst of firing (D1), but in the new position (θ_1) the eye is still too far medial for the cell to discharge continually. During the next saccade there is a burst (D2), and at the new position (θ_2) there is a tonic position-related discharge. Before and during the next saccade (D3) there is again a pulse of activity and a higher tonic discharge when the eye is at the new position (θ_4) . When the eye makes a medial movement there is a period of silence during the saccade (D4) even though the eye ends up at a position associated with a tonic discharge. (Adapted, with permission, from A. Fuchs 1970.)

B. Saccades are associated with a step of activity, which signals the change in eye position, and a pulse of activity, which signals eye velocity. The neural activity corresponding to eye position and velocity is illustrated both as a train of individual spikes and as an estimate of the instantaneous firing rate (spikes per second).

abducens nucleus to which it projects (Figure 39–9A). The paramedian pontine reticular formation contains a family of *burst neurons* that gives rise to the saccadic pulse. These cells fire at a high frequency just before and during ipsiversive saccades, and their activity resembles the pulse component of ocular motor neuron discharge (Figure 39–9B).

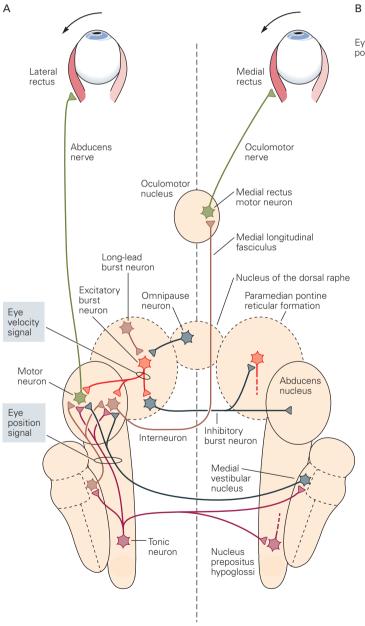

There are several types of burst neurons. Mediumlead burst neurons make direct excitatory connections to motor neurons and interneurons in the ipsilateral abducens nucleus. Long-lead burst neurons drive the medium-lead burst cells and receive excitatory input from higher centers. Inhibitory burst neurons suppress the activity of contralateral abducens neurons and contralateral excitatory burst neurons and are themselves excited by medium-lead burst neurons.

A second class of pontine cells, *omnipause neurons*, fire continuously except around the time of a saccade; firing ceases shortly before and during all saccades (Figure 39–9B). Omnipause neurons are located in

the nucleus of the dorsal raphe in the midline (Figure 39–9A). They are GABA-ergic (γ -aminobutyric acid) inhibitory neurons that project to contralateral pontine and mesencephalic burst neurons. Electrical stimulation of omnipause neurons arrests a saccade, which resumes when the stimulation stops. Making a saccade requires simultaneous excitation of burst neurons and inhibition of omnipause cells; this provides the system

with additional stability, such that unwanted saccades are infrequent.

If the motor neurons received signals from only the burst cells, the eyes would drift back to the starting position because there would be no new position signal to hold the eyes against elastic restorative forces. David A. Robinson first pointed out that the tonic position signal, the saccadic step, can be generated from

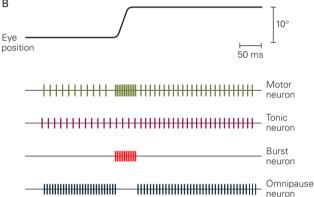

Figure 39-9 The motor circuit for horizontal saccades.

A. Eye velocity component. Long-lead burst neurons relay signals from higher centers to the excitatory burst neurons. The eye velocity component arises from excitatory burst neurons in the paramedian pontine reticular formation that synapse on motor neurons and interneurons in the abducens nucleus. The abducens motor neurons project to the ipsilateral lateral rectus muscles, whereas the interneurons project to the contralateral medial rectus motor neurons by axons that cross the midline and ascend in the medial longitudinal fasciculus. Excitatory burst neurons also drive ipsilateral inhibitory burst neurons that inhibit contralateral abducens motor neurons and excitatory burst neurons.

Eye position component. This component arises from a neural integrator comprising neurons distributed throughout the medial vestibular nuclei and nucleus prepositus hypoglossi on both sides of the brain stem. These neurons receive velocity signals from excitatory burst neurons and integrate this velocity signal to a position signal. The position signal excites the ipsilateral abducens neurons and inhibits the contralateral abducens neurons.

Gray neurons are inhibitory; all other neurons are excitatory. The vertical **dashed line** represents the midline of the brain stem.)

B. Different neurons provide different information for a horizontal saccade. The motor neuron provides both position and velocity signals. The tonic neuron (nucleus prepositus hypoglossi) signals only eye position. The excitatory burst neuron (paramedian pontine reticular formation) signals only eye velocity. The omnipause neuron discharges at a high rate except immediately before, during, and just after the saccade.

the velocity burst signal by the neural equivalent of the mathematical process of integration. Velocity can be computed by differentiating position with respect to time; conversely, position can be computed by integrating velocity with respect to time.

For horizontal eye movements, neural integration of the velocity signal is performed by the medial vestibular nucleus and the nucleus prepositus hypoglossi in conjunction with the flocculus of the cerebellum. As expected, animals with lesions of these areas make normal horizontal saccades but the eyes drift back to a middle position after a saccade. Integration of the horizontal saccadic burst requires coordination of the bilateral nuclei propositi hypoglossi and medial vestibular nuclei through commissural connections. A midline lesion of these connections causes failure of the neural integrator.

Medium-lead burst neurons in the paramedian pontine reticular formation and neurons of the medial vestibular nucleus and nucleus prepositus hypoglossi project to the ipsilateral abducens nucleus and deliver respectively the pulse and step components of the motor signal. Two populations of neurons in the abducens nucleus receive this signal. One is a group of motor neurons that innervate the ipsilateral lateral rectus muscle. The second group consists of interneurons whose axons cross the midline and ascend in the medial longitudinal fasciculus to the motor neurons for the contralateral medial rectus, which lie in the oculomotor nucleus (Figure 39–9A).

Thus, medial rectus motor neurons do not receive the pulse and step signals directly. This arrangement allows for precise coordination of corresponding movements of both eyes during horizontal saccades and other conjugate eye movements. The length of the medial longitudinal fasciculus and its vulnerability to demyelination and ischemia make it clinically important.

Vertical Saccades Are Generated in the Mesencephalic Reticular Formation

The burst neurons responsible for vertical saccades are found in the rostral interstitial nucleus of the medial longitudinal fasciculus in the mesencephalic reticular formation (see Figure 39–6). Vertical and torsional neural integration are performed in the nearby interstitial nucleus of Cajal. Both the pontine and mesencephalic systems participate in the generation of oblique saccades, which have both horizontal and vertical components.

Purely vertical saccades require activity on both sides of the mesencephalic reticular formation, and communication between the two sides occurs in the posterior commissure. In contrast, there are not separate omnipause neurons for horizontal and vertical saccades; pontine omnipause cells inhibit both pontine and mesencephalic burst neurons.

Brain Stem Lesions Result in Characteristic Deficits in Eye Movements

We can now understand how different brain stem lesions cause characteristic syndromes. Lesions that include the paramedian pontine reticular formation result in paralysis of ipsiversive horizontal gaze of both eyes but spare vertical saccades. A lesion of the abducens nucleus has a similar effect, for both abducens motor neurons and interneurons are affected. Lesions that include the midbrain gaze centers cause paralysis of vertical gaze. Certain neurological disorders cause degeneration of burst neurons and impair their function, leading to a progressive slowing of saccades.

Lesions of the medial longitudinal fasciculus disconnect the medial rectus motor neurons from the abducens interneurons (Figure 39–9A). Thus during conjugate horizontal eye movements, such as saccades and pursuit, the abducting eye moves normally but adduction of the other eye is impeded. Despite this paralysis in version movements, the medial rectus acts normally in vergence movements because the motor neurons for vergence lie in the midbrain, as will be discussed later. This syndrome, called an *internuclear ophthalmoplegia*, is a consequence of a brain stem stroke or demyelinating diseases such as multiple sclerosis.

Saccades Are Controlled by the Cerebral Cortex Through the Superior Colliculus

The pontine and mesencephalic burst circuits provide the motor signals necessary to drive the muscles for saccades. However, among higher mammals eye movements are ultimately driven by cognitive behavior. The decision when and where to make a saccade that is behaviorally important is usually made in the cerebral cortex. A network of cortical and subcortical areas controls the saccadic system through the superior colliculus (Figure 39–10).

The Superior Colliculus Integrates Visual and Motor Information into Oculomotor Signals to the Brain Stem

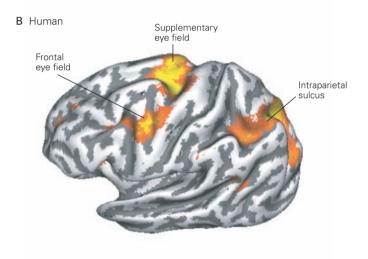

The superior colliculus in the midbrain is a major visuomotor integration region, the mammalian homolog

A Monkey Supplementary Posterior eye field parietal cortex (LIP) Frontal eve field Targets selected Cortical signals Superior relayed to motor circuits Caudate nucleus Translation into specific muscle signals for saccades Substantia nigra pars reticulata Mesencephalic and pontine reticular formations

Figure 39–10 Cortical pathways for saccades.

A. In the monkey the saccade generator in the brain stem receives a command from the superior colliculus. The colliculus receives direct excitatory projections from the frontal eye fields and the lateral intraparietal area (LIP) and an inhibitory projection from the substantia nigra. The substantia nigra is suppressed by the caudate nucleus, which in turn is excited by the frontal eye fields. Thus the frontal eye fields directly excite the colliculus and indirectly release it from suppression by the substantia nigra by exciting the caudate nucleus, which inhibits the substantia nigra. (Reproduced, with permission, from R. J. Krausliz.)

B. This lateral scan of a human brain shows areas of cortex activated during saccades. (Reproduced, with permission, from Curtis and Connelly 2010.)

of the optic tectum in nonmammalian vertebrates. It can be divided into two functional regions: the superficial layers and the intermediate and deep layers.

The three superficial layers receive both direct input from the retina and a projection from the striate cortex representing the entire contralateral visual hemifield. Neurons in the superficial layers respond to visual stimuli. In monkeys the responses of half of these vision-related neurons are quantitatively enhanced when an animal prepares to make a saccade to a stimulus in the cell's receptive field. This enhancement is specific for saccades. If the monkey attends to the stimulus without making a saccade to it—for example, by making a hand movement in response to a brightness change—the neuron's response is not augmented.

Neuronal activity in the two intermediate and deep layers is primarily related to oculomotor actions. The movement-related neurons in these layers receive visual information from the prestriate, middle temporal, and parietal cortices and motor information from the frontal eye field. The intermediate and deep layers also contain somatotopic, tonotopic, and retinotopic maps of sensory inputs, all in register with one another. For example, the image of a bird will excite a vision-related neuron, whereas the bird's chirp will excite an adjacent audition-related neuron, and both will excite a bimodal neuron. Polymodal spatial maps enable us to shift our eyes toward auditory or somatosensory stimuli as well as visual ones.

Much of the early research describing the sensory responsiveness of neurons in the intermediate layer

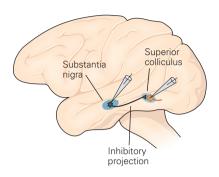

was done in anesthetized animals. To understand how the brain generates movement, however, the activity of neurons needs to be studied in alert animals while they behave normally. Edward Evarts pioneered this approach in studies of the skeletomotor system, after which it was extended to the ocular motor system.

One of the earliest cellular studies in active animals revealed that individual movement-related neurons in the superior colliculus selectively discharge before saccades of specific amplitudes and directions, just as individual vision-related neurons in the superior colliculus respond to stimuli at specific distances and directions from the fovea (Figure 39–11A). The movement-related neurons form a map of potential eye movements that is in register with the visuotopic and tonotopic arrays of sensory inputs, so that the neurons that control eve movements to a particular target are found in the same region as the cells excited by the sounds and image of that target. Each movement-related neuron in the superior colliculus has a movement field, a region of the visual field that is the target for saccades controlled by that neuron. Electrical stimulation of the intermediate layers of the superior colliculus evokes saccades into the movement fields of the stimulated neurons.

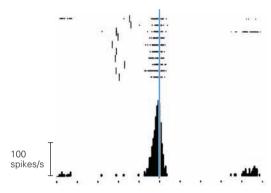

Movement fields are large, so each superior colliculus cell fires before a wide range of saccades, although each cell fires most intensely before saccades of a specific direction and amplitude. A large population of cells is thus active before each saccade, and eye movement is encoded by the entire ensemble of these broadly tuned cells. Because each cell makes only a small contribution to the direction and amplitude of the movement, any variability or noise in the discharge of a given cell is minimized. Similar population coding is found in the olfactory system (see Chapter 32) and skeletal motor system (see Chapter 37).

Activity in the superficial and intermediate layers of the superior colliculus can occur independently: Sensory activity in the superficial layers does not always lead to motor output, and motor output can occur without sensory activity in the superficial layers. In fact, the neurons in the superficial layers do not provide a large projection directly to the intermediate layers. Instead, their axons terminate on neurons in the pulvinar and lateral posterior nuclei of the thalamus, which relay the signals from the superficial layers of the superior colliculus to cortical regions that project back to the intermediate layers.

Lesions of a small part of the colliculus affect the latency, accuracy, and velocity of saccades. Destruction of the entire colliculus renders a monkey unable to make any contralateral saccades, although with time this ability is recovered.

A Superior colliculus neuron

B Substantia nigra neuron

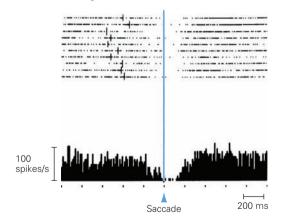

Figure 39–11 Neurons in the superior colliculus and substantia nigra are active around the time of a saccade. The two neurons were recorded simultaneously. (Reproduced, with permission, from Hikosaka and Wurtz 1989.)

A. A neuron in the superior colliculus fires in a burst immediately before the saccade. Raster plots of activity in successive trials of the same task are summed to form the histogram below.

B. A neuron in the substantia nigra pars reticulata is tonically active, becomes quiet just before the saccade, and resumes activity after the saccade. This type of neuron inhibits neurons in the intermediate layers of the superior colliculus.

The Rostral Superior Colliculus Facilitates Visual Fixation

The most rostral portion of the superior colliculus contains a representation of the fovea. Neurons in the intermediate layers in this region discharge strongly during active visual fixation and before small saccades to the contralateral visual field. Because the neurons are active during visual fixation, this area of the superior colliculus is often called the fixation zone.

Neurons here inhibit the movement-related neurons in the more caudal parts of the colliculus and also project directly to the nucleus of the dorsal raphe, where they inhibit saccade generation by exciting the omnipause neurons. With lesions in the fixation zone an animal is more likely to make saccades to distracting stimuli.

The Basal Ganglia Inhibit the Superior Colliculus

The substantia nigra pars reticulata sends a powerful GABAergic inhibitory projection to the superior colliculus. Neurons in the substantia nigra fire spontaneously with high frequency; this discharge is suppressed at the time of voluntary eye movements to the contralateral visual field (see Figure 39–11B). Suppression is mediated by inhibitory input from neurons in the caudate nucleus, which fire before saccades to the contralateral visual field.

Two Regions of Cerebral Cortex Control the Superior Colliculus

The superior colliculus is controlled by two regions of the cerebral cortex that have overlapping but distinct functions: the lateral intraparietal area of the posterior parietal cortex (part of Brodmann's area 7) and the frontal eye field (part of Brodmann's area 8). Each of these areas contributes to the generation of saccades and the control of visual attention.

Perception is better at an attended place in the visual field than at an unattended place, as measured either by a subject's reaction time to an object suddenly appearing in the visual field or by the subject's ability to perceive a stimulus that is just noticeable. Saccadic eye movements and visual attention are closely intertwined (see Figure 39–1).

The lateral intraparietal area in the monkey is important in the generation of both visual attention and saccades. The role of this area in the processing of eye movements is best illustrated by a memory-guided saccade. To demonstrate this saccade, a monkey first fixates a spot of light. An object (the stimulus) appears

in the receptive field of a neuron and then disappears; then the spot of light is extinguished. After a delay the monkey must make a saccade to the location of the vanished stimulus. Neurons in the lateral intraparietal area respond at the onset of the stimulus and continue firing during the delay until the saccade begins (Figure 39–12A), but their activity can be also dissociated from saccade planning. If the monkey is planning a saccade to a target outside the receptive field of a neuron, and a distractor appears in the field during the delay period, the neuron responds as vigorously to the distractor as it does to the target of a saccade (Figure 39–12B).

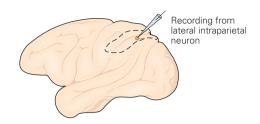

Lesioning of a monkey's posterior parietal cortex, which includes the lateral intraparietal area, increases the latency of saccades and reduces their accuracy. Such a lesion also produces selective neglect: A monkey with a unilateral parietal lesion preferentially attends to stimuli in the contralateral visual hemifield. In humans as well, parietal lesions—especially right parietal lesions—initially cause dramatic attentional deficits. Patients act as if the objects in the neglected field do not exist, and they have difficulty making eye movements into that field (see Chapter 17).

Patients with Balint syndrome, which is usually the result of bilateral lesions of the posterior parietal and prestriate cortex, tend to see and describe only one object at a time in their visual environment. These patients make few saccades, as if they are unable to shift the focus of their attention from the fovea, and can therefore describe only a foveal target. Even after these patients have recovered from most of their deficits, their saccades are delayed and inaccurate.

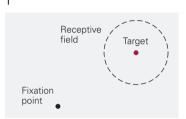

Compared to the neurons in the parietal cortex, neurons in the frontal eye field are more closely associated with saccades. Three different types of neurons in the frontal eye field discharge before saccades.

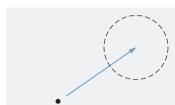

Visual neurons respond to visual stimuli and half of these neurons respond more vigorously to stimuli that are the targets of saccades (Figure 39–13A). Activity in these cells is not enhanced when an animal responds to the stimulus without making a saccade to it. Likewise, these cells are not activated before saccades that are made without visual targets; monkeys can be trained to make saccades of a specific direction and amplitude in total darkness.

Movement-related neurons fire before and during all saccades to their movement fields, whether or not they are made to a visual target. These cells do not respond to stimuli in their movement fields that are not targets of saccades. Unlike the movement-related cells in the superior colliculus, which fire before all saccades, movement-related neurons of the frontal eye field fire only before saccades that are relevant to the monkey's

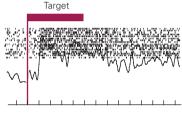

A Neuron fires from appearance of target until saccade

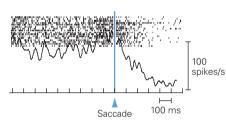

B Neuron responds as powerfully to distractor in receptive field

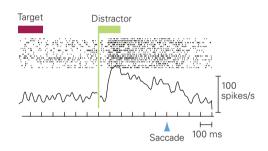

Figure 39–12 A parietal neuron is active before memoryguided saccades. Traces are aligned at events indicated by vertical lines. (Reproduced, with permission, from Powell and Goldberg 2000.)

A. The monkey plans a saccade from a fixation point to a target in the receptive field of a neuron in the lateral intraparietal cortex. The neuron responds to the appearance of the target (1).

It continues to fire after the target has disappeared but before the signal to make the saccade, and stops firing after the onset of the saccade (2).

B. The monkey plans a saccade to a target outside the receptive field. The neuron responds to a distractor in the receptive field as strongly as it did to the target of a saccade.

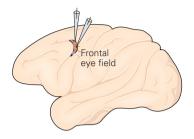

behavior (Figure 39–13B). These neurons, especially those whose receptive fields lie in the visual periphery, project more strongly to the superior colliculus than do the visual neurons.

Visuomovement neurons have both visual and movement-related activity and discharge most strongly before visually guided saccades. Electrical stimulation of the frontal eye field evokes saccades to the movement fields of the stimulated cells. Bilateral stimulation of the frontal eye field evokes vertical saccades.

The frontal eye field controls the superior colliculus through two pathways (see Figure 39–10). First, the movement-related neurons project directly to the intermediate layers of the superior colliculus, exciting movement-related neurons there. Second, movement-related neurons form excitatory synapses on neurons

in the caudate nucleus that inhibit the substantia nigra pars reticulata. Thus, activity of movement-related cells in the frontal eye field simultaneously excites the superior colliculus and releases it from the inhibitory influence of the substantia nigra. The frontal eye field also projects to the pontine and mesencephalic reticular formations, although not directly to the burst cells.

Two other cortical regions with inputs to the frontal eye field are thought to be important in the cognitive aspects of saccades. The *supplementary eye field* at the most rostral part of the supplementary motor area contains neurons that encode saccades in terms of spatial referents other than direction. For example, a neuron in the left supplementary eye field that ordinarily fires before rightward eye movements will fire before a leftward saccade if that saccade is to the right side of

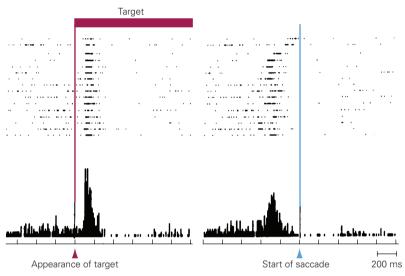

A Visual neuron responds to the stimulus and not to movement

Figure 39–13 Visual and movement-related neurons in the frontal eye field. (Reproduced, with permission, from Bruce and Goldberg 1985.)

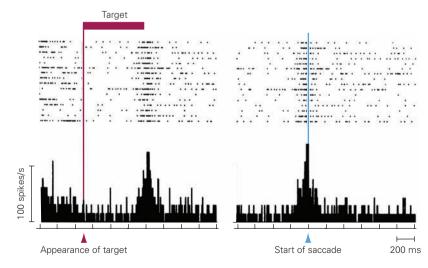

A Activity of a visual neuron in the frontal

A. Activity of a visual neuron in the frontal eye field as a monkey makes a saccade to a target in its visual field. Raster plots of activity in successive trials of the same task are summed to form the histogram below. In the record on the left the individual trials are aligned at the appearance of the stimulus. A burst of firing is closely time-locked to the stimulus. In the record on the right the trials are aligned at the beginning of the saccade. Activity is not well aligned with the beginning of the saccade and stops before the saccade itself commences.

B. Activity of a movement-related neuron in the frontal eye field. The records of each trial are aligned as in part A. The cell does not respond to appearance of the saccade target (left). However, it is active at the time of the saccade (right).

B Movement-related neuron responds before movement but not to stimulus

the target. The *dorsolateral prefrontal cortex* has neurons that discharge when a monkey makes a saccade to a remembered target. The activity commences with the appearance of the stimulus and continues throughout the interval during which the monkey must remember the location of the target.

We can now understand the effects of lesions of these regions on the generation of saccades. Lesions of the superior colliculus in monkeys produce only transient damage to the saccade system because the projection from the frontal eye field to the brain stem remains intact. Animals can likewise recover from cortical lesions if the superior colliculus is intact. However, when both the frontal eye field and the colliculus are damaged, the ability to make saccades is permanently compromised. The predominant effect of a parietal lesion is an attentional deficit. After recovery, however, the system can function normally because the frontal eye field signals are sufficient to suppress the substantia nigra and stimulate the colliculus.

Damage to the frontal eye field alone causes more subtle deficits. Lesions of the frontal eye field in monkeys cause transient contralateral neglect and paresis of contralateral gaze that rapidly recover. The latter deficit may reflect the loss of frontal eye field control of the substantia nigra; this loss of control means that the constant inhibitory input from the substantia nigra to the colliculus does not get suppressed, and the colliculus is unable to generate any saccades. Eventually the system adapts, and the colliculus responds to the remaining parietal signal. After recovery the animals have no trouble producing saccades to targets in the visual field but have great difficulty with memory-guided saccades. Bilateral lesions of both the frontal eye fields and the superior colliculus render monkeys unable to make saccades at all.

Humans with lesions of the frontal cortex have difficulty suppressing unwanted saccades to attended stimuli. This is easily shown by asking subjects to make an eye movement away from a stimulus. When the stimulus appears the subject must attend to it, without turning the eyes toward it, and use its location to calculate the desired saccade. Patients with frontal lesions cannot suppress the saccade to the stimulus, even though they can make normal saccades to visual targets.

As we have seen, neurons in the lateral intraparietal area of monkeys are active when the animal attends to a visual stimulus whether or not the animal makes a saccade to the stimulus. In the absence of frontal eye field signals this undifferentiated signal is the only one to reach the superior colliculus. In humans the failure to suppress a saccade is therefore to be expected if the superior colliculus responds to a parietal signal

that generates attention to the stimulus, without the frontal-nigral control that normally prevents saccades in response to parietal signals.

The Control of Saccades Can Be Modified by Experience

Quantitative study of the neural control of movement is possible because the discharge rate of a motor neuron has a predictable effect on a movement. For example, a certain frequency of firing in the abducens motor neuron has a predictable effect on eye position and velocity.

This relationship can change, however, if the muscle becomes weak through disease. The brain can compensate to some degree for such changes. For example, a diabetic patient may have an abducens-nerve lesion affecting one eye and a retinal hemorrhage in the other. He is forced to use the eye with the weak lateral rectus muscle because he experiences poor vision in the eye with the normal abducens nerve. If the latter eye is patched to prevent double vision, the influence of the weak eye increases, such that the weak eye is eventually able to make accurate saccades. The influence of the patched eye also increases, causing that eye to make excessively large saccades. This is of little importance to vision, however, because the patched eye does not contribute to vision. This change in the motor response depends on the fastigial nucleus and vermis of the cerebellum.

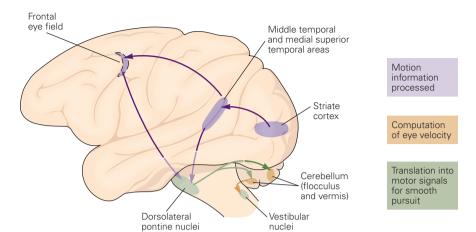

Smooth Pursuit Involves the Cerebral Cortex, Cerebellum, and Pons

The task of the smooth-pursuit system differs from that of the saccade system. Instead of driving the eyes as rapidly as possible to a point in space, it must match the velocity of the eyes to that of a target in space. Neurons that signal eye velocity for smooth pursuit are found in the medial vestibular nucleus and the nucleus prepositus hypoglossi. They project to the abducens nucleus as well as the ocular motor nuclei in the midbrain and receive projections from the flocculus of the cerebellum.

Neurons in both the vermis and flocculus transmit an eye-velocity signal that correlates with smooth pursuit (Figure 39–14). These areas receive signals from the cerebral cortex relayed by the dorsolateral pontine nucleus. Thus lesions in the dorsolateral pons disrupt ipsilateral smooth pursuit.

There are two major cortical inputs to the smoothpursuit system in monkeys. One arises from motionsensitive regions in the superior temporal sulcus and the middle temporal and medial superior temporal areas. The other arises from the frontal eye field.

Figure 39–14 Pathways for smoothpursuit eye movements in the monkey. The cerebral cortex processes information about motion in the visual field and sends it to the ocular motor neurons via the dorsolateral pontine nuclei, the vermis and flocculus of the cerebellum, and the vestibular nuclei. The initiation signal for smooth pursuit may originate in part from the frontal eye field. (Reproduced, with permission, from R. J. Krausliz.)

Neurons in both the middle temporal and medial superior temporal areas calculate the velocity of the target. When the eye accelerates to match the target's speed, the rate of the target's motion across the retina decreases. As the speed of the retinal image decreases, neurons in the middle temporal area, which describe retinal-image motion, stop firing, even though the target continues to move in space. Neurons in the medial superior temporal area continue to fire even if the target disappears briefly. These neurons have access to a process that adds the speeds of the moving eye and the target moving on the retina to compute the speed of the target in space.

Lesions of either the middle temporal or medial superior temporal area disrupt the ability of a subject to respond to targets moving in regions of the visual field represented in the damaged cortical area. Lesions of the latter area also diminish smooth-pursuit movements toward the side of the lesion, no matter where the target lies on the retina.

The temporal cortex provides the sensory information to guide pursuit movements but may not be able to initiate them. Electrical stimulation of either temporal area does not initiate smooth pursuit but can affect pursuit movement, accelerating ipsilateral pursuit and slowing contralateral pursuit. The frontal eye field may be more important for initiating pursuit. This area has neurons that fire in association with ipsilateral smooth pursuit. Electrical stimulation of the frontal eye field initiates ipsilateral pursuit, whereas lesions of the frontal eye field diminish, but do not eliminate, smooth pursuit.

In humans, disruption of the pursuit pathway anywhere along its course, including lesions at the level of cortical, cerebellar, and brain stem areas, prevents adequate smooth-pursuit eye movements. Instead, moving targets are tracked using a combination of

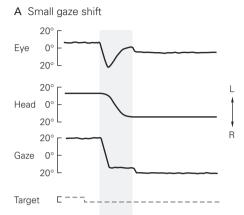

defective smooth-pursuit movements, whose velocity is less than that of the target, and small saccades. Patients with brain stem and cerebellar lesions cannot pursue targets moving toward the side of the lesion.

Patients with parietal deficits have two different types of deficit. The first is a directional deficit that resembles that of monkeys with lesions of the middle superior temporal area: Targets moving toward the side of the lesion cannot be tracked. The second is a retinotopic deficit that resembles the deficit of monkeys with lesions of the medial temporal area. Normal subjects can generate smooth-pursuit eye velocity to match the velocity of a stimulus in the periphery (see Figure 39–2). Most patients cannot generate smooth pursuit of a stimulus limited to the visual hemifield opposite the lesion, regardless of the direction of motion.

Some Gaze Shifts Require Coordinated Head and Eye Movements

So far we have described how the eyes are moved when the head is still. When we look around, however, our head is moving as well. Head and eye movements must be coordinated to direct the fovea to a target.

Because the head has a much greater inertia than the eyes, a small shift in gaze drives the fovea to its target before the head begins to move. A small gaze shift usually consists of a saccade followed by a small head movement during which the vestibulo-ocular reflex moves the eyes back to the center of the orbit in the new head position (Figure 39–15). For larger gaze shifts, the eyes and the head move simultaneously in the same direction. Because the vestibulo-ocular reflex ordinarily moves the eyes in the direction opposite

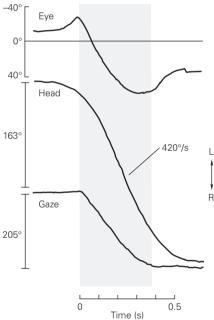

Figure 39–15 Directing the fovea to an object when the head is moving requires coordinated head and eye movements.

A. For a small gaze shift, the eye and head move in sequence. The eye begins to move 300 ms after the target appears. Near the end of the eye movement, the head begins to move as well. The eye then rotates back to the center of the orbit to compensate for the head movement. The gaze record is the sum of eye and head movements. (Reproduced, with permission, from Zee 1977.)

B. For a large gaze shift the eye and head move in the same direction simultaneously. Near the end of the gaze shift the vestibulo-ocular reflex returns, the eye begins to compensate for head movement as in A, and gaze becomes still. (Reproduced, with permission, from Laurutis and Robinson 1986.)

that of the head, the reflex must be temporarily suppressed for the eyes and head to move simultaneously.

Many of the neural centers that control simple saccades also control gaze shift. Electrical stimulation of the superior colliculus in a monkey with its head fixed evokes saccades, but stimulation of an animal whose head can move freely results in saccades combined with head movement. Neurons in the superior colliculus that carry eye-movement signals also project to neurons in the reticular formation that drive the neck muscles, presumably enabling a combined head and eye movement to position the fovea on an object of interest.

An Overall View

The oculomotor system provides a valuable window into the nervous system for both the clinician and the scientist. Patients with oculomotor deficits experience double vision, an alarming symptom that quickly sends them to seek medical help. A physician with a thorough knowledge of the oculomotor system can describe and diagnose most oculomotor deficits at the bedside and localize the site of the lesion within the brain based on the neuroanatomy and neurophysiology of eye movements. Much of our understanding of neural processes arises from our knowledge of the oculomotor system as a microcosm of human behavior.

The cerebral cortex chooses significant objects in the environment as targets for eye movements. Cortical signals are relayed to motor circuits in the brain stem by the superior colliculus. The cortical and collicular signals do not specify the contribution of each muscle to the movement. Instead, the motor programming for eye movements is performed in the brain stem, which translates the signals from higher centers into signals appropriate for each muscle. The cerebellum plays an important role in calibrating eye-muscle movement.

IRPLANES AND SUBMARINES navigate in three dimensions using sophisticated guidance systems that register every acceleration and turn. Laser gyroscopes and computers make these navigational aids extremely precise. Yet the principles of inertial guidance are ancient: Vertebrates have used analogous systems for 500 million years and invertebrates for still longer.

In vertebrates the inertial guidance system is the vestibular system, comprising five sensory organs in the internal ear that measure linear and angular acceleration of the head. Acceleration of the head deflects hair bundles protruding from the hair cells in the inner ear; this distortion changes the cells' membrane potential, altering the synaptic transmission between the cells and the sensory neurons that innervate them. The signals from these vestibular neurons convey information on head velocity and acceleration to vestibular nuclei in the brain stem.

This information keeps the eyes still when the head moves, helps to maintain upright posture, and influences how we perceive our own movement and the space around us by providing a measure of the gravitational field in which we live. In this chapter we describe how the hair cells of the inner ear generate the signals for head acceleration and how these signals are integrated with other sensory information in the brain.

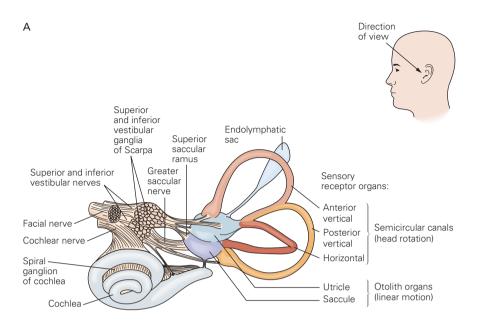

The Vestibular Apparatus in the Inner Ear Contains Five Receptor Organs

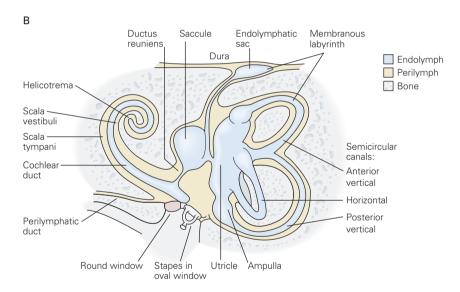

Vestibular signals originate in the labyrinths of the internal ear (Figure 40–1). The *bony labyrinth* is a hollow structure within the petrous portion of the temporal

Figure 40–1 The vestibular apparatus of the inner ear.

A. The orientations of the vestibular and cochlear divisions of the inner ear are shown with respect to the head.

B. The inner ear is divided into bony and membranous labyrinths. The bony labyrinth is bounded by the petrous portion of the temporal bone. Lying within this structure is the membranous labyrinth, which contains the receptor organs for hearing (the cochlea) and equilibrium (the utricle, saccule, and semicircular canals). The space between bone and membrane is filled with perilymph, whereas the membranous labyrinth is filled with endolymph. Sensory cells in the utricle, saccule, and ampullae of the semicircular canals respond to motion of the head. (Adapted, with permission, from lurato 1967.)

bone. Within it lies the *membranous labyrinth*, which contains sensors for both the vestibular and auditory systems.

The membranous labyrinth is filled with *endolymph*, a Na⁺-poor, K⁺-rich fluid whose composition is maintained by the action of ion pumps in specialized cells. Surrounding the membranous labyrinth, in the space between the membranous labyrinth and the wall of the bony labyrinth, is *perilymph*. Perilymph is a high-Na⁺, low-K⁺ fluid similar in composition to cerebrospinal fluid, with which it is in communication through the cochlear aqueduct. The endolymph and perilymph

are kept separate by a junctional complex that girdles the apex of each cell.

During development the labyrinth progresses from a simple sac to a complex of interconnected sensory organs but retains the same fundamental topological organization. Each organ originates as an epithelium-lined pouch that buds from the otic cyst, and the endolymphatic spaces within the several organs remain continuous in the adult. The endolymphatic spaces of the vestibular labyrinth are also connected to the cochlear duct through the ductus reuniens (Figure 40–1B).

The vestibular portion of the labyrinth, or vestibular apparatus, lies posterior to the cochlea and consists of five sensory structures. Three *semicircular canals* (*horizontal*, also called lateral; *anterior*, also called superior; and *posterior*) sense head rotations, whereas two otolith organs (*utricle* and *saccule*) sense linear motion (also called translation). Because gravity is a linear acceleration, the otolith organs also sense the orientation, or tilt, of the head relative to gravity.

Hair Cells Transduce Mechanical Stimuli into Receptor Potentials

Each of the five receptor organs has a cluster of hair cells responsible for transducing head motion into vestibular signals. Angular or linear acceleration of the head leads to a deflection of the hair bundles in a particular group of hair cells of the appropriate receptor organ (Figure 40–2).

Vestibular signals are carried from the hair cells to the brain stem by branches of the vestibulocochlear nerve (cranial nerve VIII). Cell bodies of the vestibular nerve are located in the vestibular ganglia of Scarpa within the internal auditory canal (Figure 40–1A). The superior vestibular nerve innervates the horizontal and anterior canals and the utricle, whereas the inferior vestibular nerve innervates the posterior canal and the saccule. The labyrinth's vascular supply, which arises from the anterior inferior cerebellar artery, mirrors its innervation: The anterior vestibular artery supplies the structures innervated by the superior vestibular nerve, and the posterior vestibular artery supplies the structures innervated by the inferior vestibular nerve.

Like most other hair cells, those of the human vestibular system receive efferent inputs from the brain stem. Although the effect of these inputs has not been extensively studied by recording from hair cells in situ, stimulation of the fibers from the brain stem changes the sensitivity of the afferent axons from the hair cells. Stimulation decreases the excitability of some hair cells, as would be expected if activation of the efferent fibers elicited inhibitory postsynaptic potentials in hair cells. In other hair cells, however, activation of the efferent fibers increases excitability.

Given that hair cells are essentially strain gauges (see Chapter 30), the key to grasping how the vestibular organs operate is to understand how mechanical stimuli are delivered to the constituent hair cells. Distinctive mechanical linkages in the otolith organs and semicircular canals account for the contrasting sensitivities of the two types of vestibular organs.

The Semicircular Canals Sense Head Rotation

An object undergoes angular acceleration when its rate of rotation about an axis changes. The head therefore undergoes angular acceleration when it turns or tilts, when the body rotates, and during active or passive locomotion. The three semicircular canals of each vestibular labyrinth detect these angular accelerations and report their magnitudes and orientations to the brain.

Each semicircular canal is a roughly semicircular tube of membranous labyrinth extending from the utricle. One end of each canal is open to the utricle whereas at the other end, the ampulla, the entire lumen of the canal is traversed by a gelatinous diaphragm, the cupula. The cupula is attached to the epithelium along the perimeter and numerous hair bundles insert into the cupula (Figure 40–3).

The vestibular organs detect accelerations of the head because the inertia of their internal contents

Figure 40–2 Hair cells in the vestibular labyrinth transduce mechanical stimuli into neural signals. At the apex of each cell is a hair bundle, the stereocilia of which increase in length toward a single kinocilium. The membrane potential of the receptor cell depends on the direction in which the hair bundle is bent. Deflection toward the kinocilium causes the cell to depolarize and thus increases the rate of firing in the afferent fiber. Bending away from the kinocilium causes the cell to hyperpolarize, thus decreasing the afferent firing rate. (Adapted, with permission, from Flock 1965.)

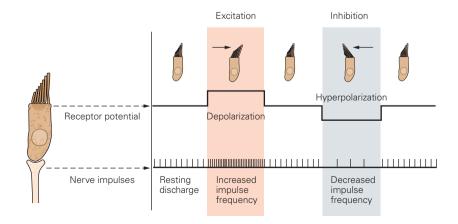

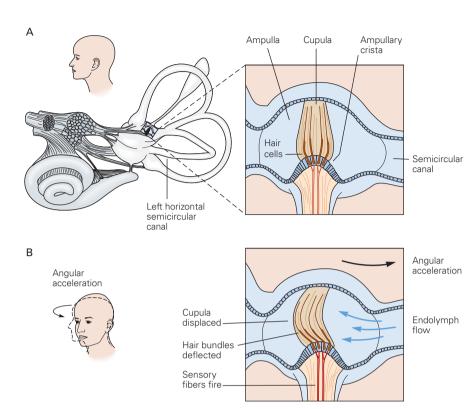

Figure 40–3 The ampulla of a semicircular canal.

A. A thickened zone of epithelium, the ampullary crista, contains the hair cells. The hair bundles of the hair cells extend into a gelatinous diaphragm, the cupula, which stretches from the crista to the roof of the ampulla.

B. The cupula is displaced by the flow of endolymph when the head moves. As a result, the hair bundles are also displaced. Their movement is greatly exaggerated in the diagram.

results in forces on their hair cells. Consider the simplest situation, a rotation in the plane of a semicircular canal. When the head begins to rotate, the membranous and bony labyrinths move along with it. Because of its inertia, however, the endolymph lags behind the surrounding membranous labyrinth, thus rotating within the canal in a direction opposite that of the head.

The motion of endolymph in a semicircular canal can be demonstrated with a cup of coffee. While gently twisting the cup about its vertical axis, observe a particular bubble near the fluid's outer boundary. As the cup begins to turn, the coffee tends to maintain its initial orientation in space and thus counter-rotates in the vessel. If you continue rotating the cup at the same speed, the coffee (and the bubble) eventually catch up to the cup and rotate with it. When the cup decelerates and stops, the coffee keeps rotating, moving in the opposite direction relative to the cup.

In the ampulla this relative motion of the endolymph creates pressure on the cupula, bending it toward or away from the adjacent utricle, depending on the direction of endolymph flow. The resulting deflection of the stereocilia alters the membrane potential of the hair cells, thereby changing the firing rates of the associated sensory fibers. The stereocilia are

arranged so that endolymph flow toward the cupula is excitatory for the horizontal canals, whereas flow away from the cupula is excitatory for the anterior and posterior vertical canals.

Each semicircular canal is maximally sensitive to rotations in its plane. The horizontal canal is oriented roughly in the horizontal plane, rising slightly from posterior to anterior, and thus is most sensitive to rotations in the horizontal plane. The anterior and posterior canals are oriented more vertically, approximately 45 degrees from the sagittal plane (Figure 40–4).

Because there is approximate mirror symmetry of the left and right labyrinths, the six canals effectively operate as three coplanar pairs. The two horizontal canals form one pair; each of the other pairs consists of one anterior canal and the contralateral posterior canal. The canal planes are also roughly the pulling planes of the eye muscles. The pair of horizontal canals lies in the pulling plane of the lateral and medial rectus muscles. The left anterior and right posterior pair lies in the pulling plane of the left superior and inferior rectus and right superior and left posterior pair occupies the pulling plane of the left superior and inferior oblique and right superior and inferior rectus muscles.

The Otolith Organs Sense Linear Accelerations

The vestibular system must compensate not only for head rotations but also for linear motion. The two oto-lith organs, the utricle and saccule, detect linear motion as well as the static orientation of the head relative to gravity, which is itself a linear acceleration. Each organ consists of a sac of membranous labyrinth approximately 3 mm in the longest dimension. The hair cells of each organ are arranged in a roughly elliptical patch called the *macula*. The human utricle contains approximately 30,000 hair cells, whereas the saccule contains some 16,000.

The hair bundles of the otolithic hair cells extend into a gelatinous sheet, the *otolithic membrane*, that covers the entire macula (Figure 40–5). Embedded on the surface of this membrane are fine, dense particles of calcium carbonate called *otoconia* ("ear dust"), which give the otolith ("ear stone") organs their name. Otoconia are typically 0.5 to 10 μ m long; millions of these particles are attached to the otolithic membranes of the utricle and saccule.

Gravity and other linear accelerations exert shear forces on the otoconial matrix and the gelatinous otolithic membrane, which can move relative to the membranous labyrinth. This results in a deflection of the hair bundles, altering activity in the

vestibular nerve to signal linear acceleration owing to translational motion or gravity. The orientations of the otolith organs and the directional sensitivity of individual hair cells are such that a linear acceleration along any axis can be sensed. For example, with the head in its normal position, the macula of each utricle is approximately horizontal. Any substantial acceleration in the horizontal plane excites some hair cells in each utricle and inhibits others, according to their orientations (Figure 40–6).

In some instances the vestibular input from a receptor may be ambiguous. For example, acceleration signals from the otolith organs do not distinguish between linear acceleration owing to translation and acceleration owing to gravity (Figure 40–7). The brain, however, integrates inputs from the semicircular canals, otolith organs, and visual and somatosensory systems to properly interpret head and body motions.

The operation of the paired saccules resembles that of the utricles. The hair cells represent all possible orientations within the plane of each macula, but the maculae are oriented vertically in nearly parasagittal planes. The saccules are therefore especially sensitive to vertical accelerations including gravity. Certain saccular hair cells also respond to accelerations in the horizontal plane, in particular those along the anterior–posterior axis.

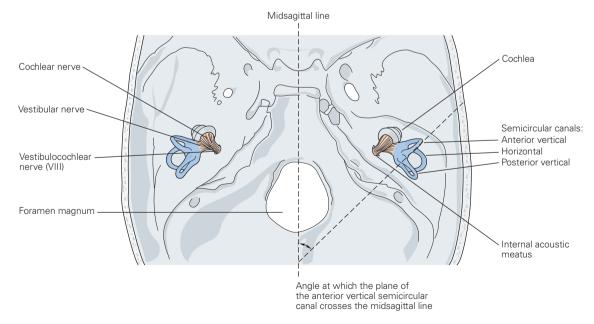

Figure 40–4 The bilateral symmetry of the semicircular canals. The horizontal canals on both sides lie in approximately the same plane and therefore are functional pairs. The bilateral

vertical canals have a more complex relationship. The anterior canal on one side and the posterior canal on the opposite side lie in parallel planes and therefore constitute a functional pair.

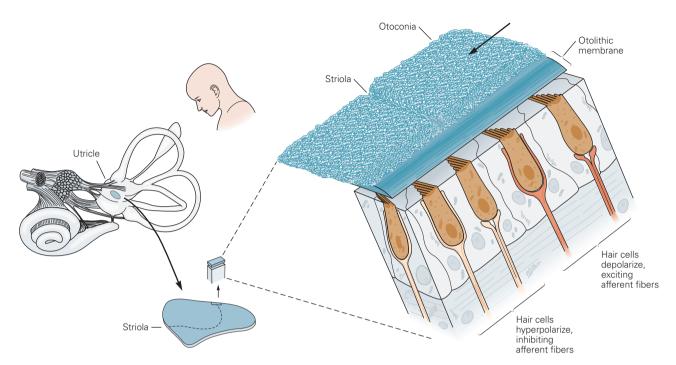

Figure 40–5 The utricle is organized to detect tilt of the head. Hair cells in the epithelium of the utricle have apical hair bundles that project into the otolithic membrane, a gelatinous material that is covered by millions of calcium carbonate particles (otoconia). The hair bundles are polarized but are oriented in different directions (see Figure 40–6). Thus when the head

is tilted, the gravitational force on the otoconia bends each hair bundle in a particular direction. When the head is tilted in the direction of a hair cell's axis of polarity, that cell depolarizes and excites the afferent fiber. When the head is tilted in the opposite direction, the same cell hyperpolarizes and inhibits the afferent fiber. (Adapted, with permission, from lurato 1967.)

Most Movements Elicit Complex Patterns of Vestibular Stimulation

Although the actions of the vestibular organs may be separated conceptually and experimentally, actual human movements generally elicit a complex pattern of excitation and inhibition in several receptor organs in both labyrinths. Consider, for example, the act of leaving the driver's seat of an automobile.

As you begin to swivel toward the door, both horizontal semicircular canals are stimulated strongly. The simultaneous lateral movement out the car's door stimulates hair cells in both utricles in a pattern that changes continuously as the orientation of the turning head changes with respect to the direction of bodily movement. When rising to a standing position, the vertical acceleration excites an appropriately oriented complement of hair cells in each of the saccules while inhibiting an oppositely oriented group. Finally, the maneuver's conclusion involves linear and angular accelerations opposite to those when you started to leave the car.

Vestibulo-Ocular Reflexes Stabilize the Eyes and Body When the Head Moves

The vestibular nerve transmits information about head acceleration to the vestibular nuclei in the medulla, which then distribute it to higher centers. This central network of vestibular connections is responsible for the vestibulo-ocular reflexes that the body uses to compensate for head movement. These neurons also determine the perception of the body's motion in space. Vestibular signals also enable the skeletal motor system to compensate for head movement. The vestibulospinal reflexes are discussed in Chapter 41.

Stable images on the retina are perceived better than moving ones. When the head moves, the eyes are kept still by the vestibulo-ocular reflexes. If you shake your head while reading you can still discern words because of the vestibulo-ocular reflexes. If instead you move the book at a similar speed, however, you can no longer read the words. In the latter instance vision is the brain's only cue for stabilization of the image

on the retina, and visual processing is much slower and less effective than vestibular processing for image stabilization. The vestibular apparatus signals how fast the head is rotating, and the oculomotor system uses this information to stabilize the eyes to fix visual images on the retina.

There are three different vestibulo-ocular reflexes. The *rotational vestibulo-ocular reflex* compensates for head rotation and receives its input predominantly from the semicircular canals. The *translational vestibulo-ocular reflex* compensates for linear head movement. The *ocular counter-rolling response* compensates for head tilt in the vertical plane.

The Rotational Vestibulo-Ocular Reflex Compensates for Head Rotation

When the semicircular canals sense head rotation in one direction, the eyes usually begin to rotate in the opposite direction in the orbits. Ideally, eye velocity is matched to head velocity, minimizing retinal motion. This compensatory eye rotation is called the *vestibular slow phase*, although it is not necessarily slow: The eyes may reach speeds of more than 200 degrees per second if the head's rotation is fast. With continued head rotation the eyes would eventually reach the limit of their orbital range and stop moving. To prevent this, a rapid saccade-like movement called a *quick phase* displaces the eyes to a new point of fixation in the direction of head rotation.

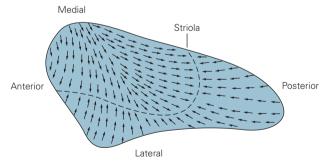

Figure 40–6 The axis of mechanical sensitivity of each hair cell in the utricle is oriented toward the striola. The striola curves across the surface of the macula, resulting in a characteristic variation in the axes of mechanosensitivity (arrows) in the population of hair cells. Because of this arrangement, tilt in any direction depolarizes some cells and hyperpolarizes others, while having no effect on the remainder. (Adapted, with permission, from Spoendlin 1966.)

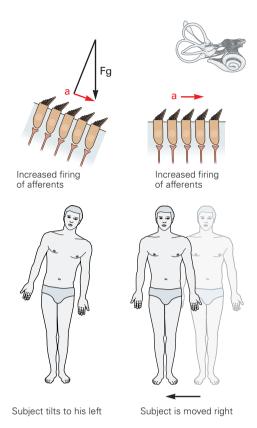

Figure 40–7 Vestibular inputs signalling body posture and motion can be ambiguous. The postural system cannot distinguish between tilt and linear acceleration of the body based on otolithic inputs alone. The same shearing force acting on vestibular hair cells can result from tilting of the head (left), which exposes the hair cells to a portion of the acceleration (a) owing to gravity (Fg), or from horizontal linear acceleration of the body (right).

If rotation is prolonged, the eyes execute alternating slow and quick phases called *nystagmus* (Greek *nod*), so called because a nod has a slow phase as the head drops and a quick phase as the head snaps back to an erect position (Figure 40–8). Although the slow phase is the primary response of the rotational vestibulo-ocular reflex, the direction of nystagmus is defined in clinical practice by the direction of its quick phase. Thus, rightward rotation excites the right horizontal canal and inhibits the left horizontal canal. This leads to leftward slow phases and a *right-beating nystagmus*.

If the angular velocity of the head remains constant, the inertia of the endolymph is eventually overcome, as in the coffee cup example earlier: The cupula relaxes and vestibular nerve discharge returns to its

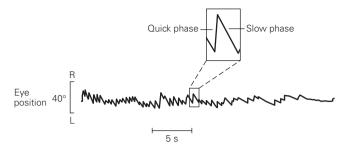

Figure 40–8 Vestibular nystagmus. The trace shows the eye position of a subject in a chair rotated counterclockwise at a constant rate in the dark. At the beginning of the trace the eye moves slowly at the same speed as the chair (slow phase) and occasionally makes rapid resetting movements (quick phase). The speed of the slow phase gradually decreases until the eye no longer moves regularly. (Reproduced, with permission, from Leigh and Zee 1991.)

baseline rate. As a consequence, slow-phase velocity decays and the nystagmus stops, although the head is still rotating.

In fact, the nystagmus lasts longer than would be expected based on cupular deflection. By a process called *velocity storage*, a brain stem network provides a velocity signal to the oculomotor system, although the vestibular nerve no longer signals head movement. Eventually, however, the nystagmus does decay and the sense of motion vanishes.

If head rotation stops abruptly, the endolymph continues to move in the same direction that the head had formerly rotated. With rightward rotation this inhibits the right horizontal canal and excites the left horizontal canal, resulting in a sensation of leftward rotation and a corresponding left-beating nystagmus. However, this occurs only in darkness. In the light, optokinetic reflexes maintain nystagmus as vestibular input diminishes, as long as the head continues to rotate. Correspondingly, optokinetic reflexes suppress post-rotatory nystagmus in the light.

The Otolithic Reflexes Compensate for Linear Motion and Head Deviations

The semicircular canals detect only head rotation; linear motion is sensed by the otolith organs. Linear movement presents the vestibular system with a more complex geometrical problem than does rotation.

When the head rotates, all images move with the same velocity on the retina. When the head moves sideways, however, the image of a close object moves more rapidly across the retina than does the image of a distant object. This can be understood easily by considering what happens when a person looks out the side window of a moving car: Objects near the side of the road move out of view almost with the speed of the car, whereas distant objects disappear more slowly. To compensate for linear head movement the vestibular system must take into account the distance to the object being viewed—the more distant the object, the smaller the eye movement.

Because gravity exerts a constant linear acceleration force on the head, the otolith organs also sense the orientation of the head relative to gravity. When the head tilts away from the vertical in the roll plane—around the axis running from the occiput to the nose—the eyes rotate in the opposite direction, along the axis of torsion, to reduce the tilt of the retinal image. This torsional eye rotation in response to head tilt is the ocular counter-rolling reflex.

Vestibulo-Ocular Reflexes Are Supplemented by Optokinetic Responses

The vestibulo-ocular reflexes represent movement imperfectly. They are best at sensing the onset or abrupt change of motion; they compensate poorly for sustained motion at constant speed during translation or constant angular velocity during rotation. In addition, they are insensitive to very slow rotations or linear accelerations.

Thus vestibular responses during prolonged motion in the light are supplemented by two visual following reflexes that maintain nystagmus when there is no longer any vestibular input. *Optokinetic nystagmus* refers to the response to full-field visual motion; *pursuit* involves the fovea following a small target. Although the two reflexes are distinct, their pathways overlap.

Central Connections of the Vestibular Apparatus Integrate Vestibular, Visual, and Motor Signals

The Vestibular Nerve Carries Information on Head Velocity to the Vestibular Nuclei

When the head is at rest there is a spontaneous tonic discharge in the bilateral vestibular nerves that is equal on both sides. That there is no imbalance in the firing rates indicates to the brain that the head is not moving. When the head rotates, the horizontal canal toward which the head is turning is excited whereas the opposite canal is inhibited, resulting in phasic increases and

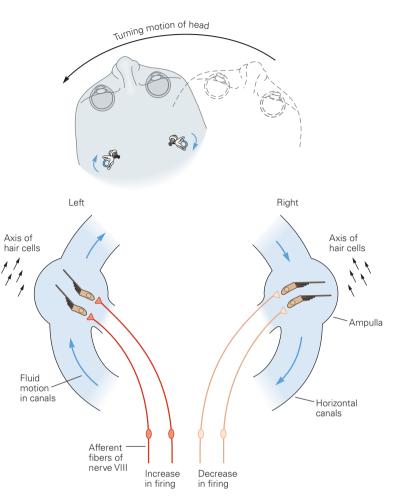

Figure 40–9 The left and right horizontal semicircular canals work together to signal head movement. Because of inertia, rotation of the head in a counterclockwise direction causes endolymph to move clockwise with respect to the canals. This deflects the stereocilia in the left canal in the excitatory direction, thereby exciting the afferent fibers on this side. In the right canal the afferent fibers are hyperpolarized so that firing decreases.

decreases in the vestibular signal (Figure 40–9). The phasic signal correlates with head velocity.

The vestibular nerve projects ipsilaterally from the vestibular ganglion to four *vestibular nuclei* in the dorsal part of the pons and medulla, in the floor of the fourth ventricle. These nuclei integrate signals from the vestibular organs with signals from the spinal cord, cerebellum, and visual system. They project in turn to several central targets: the oculomotor nuclei, reticular and spinal centers concerned with skeletal movement, the vestibular regions of the cerebellum (flocculus, nodulus, ventral paraflocculus, and ventral uvula), and the thalamus. In addition, each vestibular nucleus projects to other vestibular nuclei, both ipsilateral and contralateral.

The vestibular nuclei—medial, lateral, superior, and descending—were originally distinguished by their cytoarchitecture. Their anatomical differences correspond approximately to functional differences (Figure 40–10).

The superior and medial vestibular nuclei receive fibers predominantly from the semicircular canals. They send fibers to oculomotor centers and to the spinal cord. Neurons in the medial vestibular nucleus are predominantly excitatory, whereas those in the superior vestibular nucleus are chiefly inhibitory. These nuclei are concerned primarily with reflexes that control gaze (see Chapter 39).

The lateral vestibular nucleus (Deiters' nucleus) receives fibers from the semicircular canals and otolith organs and projects mostly into the lateral vestibulospinal tract. This nucleus is concerned principally with postural reflexes. The descending vestibular nucleus receives predominantly otolithic input and projects to the cerebellum and reticular formation as well as to the contralateral vestibular nuclei and the spinal cord. This nucleus is thought to be involved in integrating vestibular signals with central motor information. Vestibular projections to the spinal systems are discussed in Chapter 41.

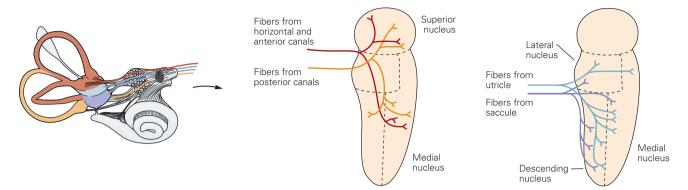

Figure 40–10 Sensory inputs to the vestibular nuclei. Neurons in the superior and medial vestibular nuclei receive input predominantly from the semicircular canals but also from the otolith organs. Neurons in the lateral vestibular nucleus (Deiters' nucleus) receive input from the semicircular canals

and otolith organs. This nucleus is concerned predominantly with postural reflexes. The descending vestibular nucleus receives input predominantly from the otolith organs. (Adapted, with permission, from Gacek and Lyon 1974.)

A Brain Stem Network Connects the Vestibular System with the Oculomotor System

During fast head movements the vestibulo-ocular reflex must act quickly to maintain stable gaze. A disynaptic brain stem pathway, the three-neuron arc, connects each semicircular canal to the appropriate eye muscle (Figure 40–11). A direct pathway for the horizontal vestibulo-ocular reflex, the ascending tract of Deiters, is anatomically significant but may not be physiologically important. Even when Deiters' tract is intact, lesions of the medial longitudinal fasciculus impair the contribution of the medial rectus muscle to the horizontal vestibulo-ocular reflex.

The oculomotor centers for vertical and torsional movements lie in the mesencephalic reticular formation (see Chapter 39). Networks similar to those for the horizontal canals connect the vertical canals to their oculomotor targets.

These excitatory and inhibitory pathways of the vestibulo-ocular reflex connect each of the three pairs of semicircular canals to the four extraocular muscles, two for each eye, whose pulling directions are in roughly the same plane. For example, a leftward and downward head motion, such as tilting the head toward the front of the left shoulder, excites the left anterior canal and inhibits the right posterior canal. In turn, the left anterior canal excites the left superior rectus and right inferior oblique muscles, which move the eyes upward and to the right, and inhibits the left inferior rectus and right superior oblique muscles, which move the eyes downward and to the left. Simultaneously, the

inhibited right posterior canal decreases its excitation of the left inferior rectus and right superior oblique, which move the eyes downward and to the left, and decreases its inhibition of the left superior rectus and right inferior oblique, which move the eyes upward and to the left. The primary muscle targets of the three canals are listed in Table 40–1.

Less is known of the central pathways mediating otolithic reflexes (translational vestibulo-ocular reflexes). Patients with cerebellar disease often have diminished vestibulo-ocular responses to linear motion but not rotation of the head, suggesting that the cerebellum is essential for the translational vestibulo-ocular reflexes.

Two Visual Pathways Drive the Optokinetic Reflexes

As we have seen, movement of images on the retina or head movement can induce nystagmus and the perception of self-motion. This perception occurs because vision-related neurons project to the vestibular nuclei. Retinal neurons project to the accessory optic system and the nucleus of the optic tract in the pretectum, which project to the same medial vestibular nucleus that receives signals from vestibular organs. Vestibular neurons that receive this visual input cannot distinguish between visual and vestibular signals (Figure 40–12). They respond identically to head movement and to motion of an image across the retina, which is presumably why people sometimes cannot distinguish the two.

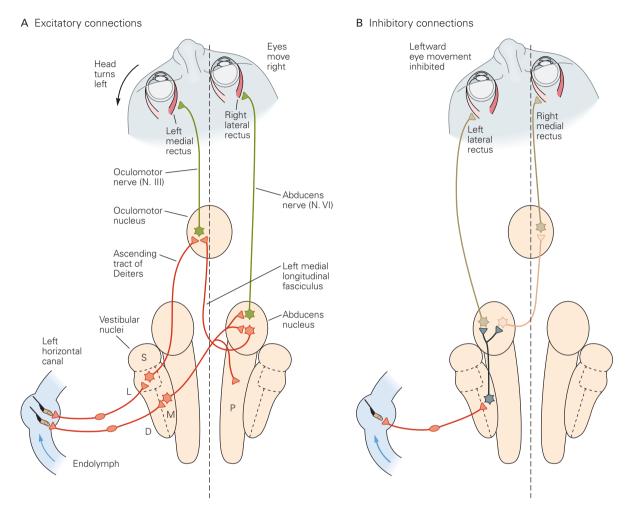

Figure 40–11 The horizontal vestibulo-ocular reflex. Similar pathways connect the anterior and posterior canals to the vertical recti and oblique muscles.

A. Leftward head rotation excites hair cells in the left horizontal canal, thus exciting neurons that evoke rightward eye movement. The vestibular nuclei include two populations of first-order neurons. One lies in the medial vestibular nucleus (M); its axons cross the midline and excite neurons in the right abducens nucleus and nucleus prepositus hypoglossi (P). The other population is in the lateral vestibular nucleus (L); its axons ascend ipsilaterally in the tract of Deiters and excite neurons in the left oculomotor nucleus, which project in the oculomotor nerve to the left medial rectus muscle.

The right abducens nucleus has two populations of neurons. A set of motor neurons projects in the abducens nerve and excites the right lateral rectus muscle. The axons of a set of interneurons cross the midline and ascend in the left medial longitudinal fasciculus to the oculomotor nucleus, where they

excite the neurons that project to the left medial rectus muscle. These connections facilitate the rightward horizontal eye movement that compensates for leftward head movement. Other nuclei shown are the superior (S) and descending (D) vestibular nuclei.

B. During counterclockwise head movement, leftward eye movement is inhibited by sensory fibers from the left horizontal canal. These afferent fibers excite neurons in the medial vestibular nucleus that inhibit motor neurons and interneurons in the left abducens nucleus. This action reduces the excitation of the motor neurons for the left lateral and right medial rectus muscles. The same head movement results in a decreased signal in the right horizontal canal (not shown), which has similar connections. The weakened signal results in decreased inhibition of the right lateral and left medial rectus muscles and decreased excitation of the left lateral and right medial rectus muscles. (Adapted, with permission, from Suguichi et al. 2005.)

Table 40–1 Primary Muscle Targets of the Semicircular Canals

Canal	Ipsilateral muscles	Contralateral muscles
Horizontal	Excite medial rectus Inhibit lateral rectus	Excite lateral rectus Inhibit medial rectus
Anterior	Excite superior rectus Inhibit inferior rectus	Excite inferior oblique Inhibit superior oblique
Posterior	Excite superior oblique Inhibit inferior oblique	Excite inferior rectus Inhibit superior rectus

In rabbits, which are lateral-eyed and afoveate, optokinetic reflexes depend primarily on brain stem pathways involving the pretectal visual system. The rabbit optokinetic response is stronger when the image moves in a temporal-to-nasal direction and is relatively more efficient at low image speeds. The same asymmetry is seen in human infants and in patients with

certain abnormalities of visual development, such as hereditary achromatopsia. Such asymmetries disappear in adult humans and nonhuman primates, which have well-developed binocular vision and thus a powerful cortical projection to the pretectum.

The Cerebral Cortex Integrates Vestibular, Visual, and Somatosensory Inputs

All vestibular nuclei project to the ventral posterior and ventral lateral nuclei of the thalamus, which then project to two regions in the primary somatosensory cortex (S-I): the vestibular regions of areas 2 and 3a (Figure 40–13). Vernon Mountcastle first showed that electrical stimulation of the vestibular nerve in the cat evoked activity in the primary somatosensory cortex (S-I) and in a parietal association cortex (area 7). Otto-Joachim Grüsser described neurons in areas 2 and 3a of the monkey that respond to head rotation. Vestibular activity has also been found in the monkey in the parieto-insular vestibular cortex, which is near the secondary somatosensory area (S-II), and in the periarcuate regions of the frontal lobe.

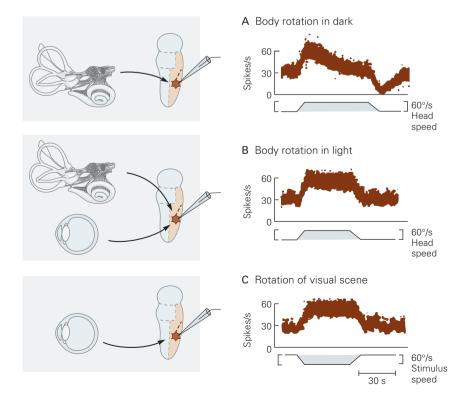

Single-cell recordings in animals have shown that these areas receive not only vestibular but also visual and somatosensory inputs. This arrangement likely

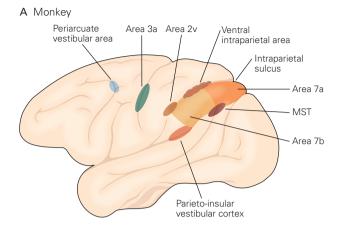

Figure 40–12 Individual neurons in the medial vestibular nucleus of a monkey receive both visual and vestibular signals. Each panel shows the spike rate of a single neuron over time. The angular velocity of the turntable used to rotate the subject or visual scene is shown below the plot. (Adapted, with permission, from Waespe and Henn 1977.)

A. When the animal is rotated in the dark, the activity of the neuron gradually falls to the baseline even while the animal is still rotating.

B. When the animal is rotated in the light, the discharge is maintained throughout rotation

C. When the animal is still while the visual scene rotates around it, the neuron in the steady state responds as if the animal were rotating in the light, although it takes somewhat longer for the neuron to reach a constant level of activity. The similarity of response between body rotation in the light and rotation of the visual scene may explain why people sometimes feel they are moving when in fact the visual scene is moving.

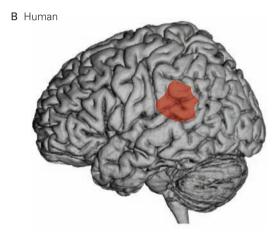

Figure 40-13 The vestibular cortex.

A. This lateral view of a monkey's brain shows the areas of cerebral cortex in which vestibular responses have been recorded. (MST, medial superior temporal area.)

B. Areas of human cortex that respond selectively to galvanic stimulation of the vestibular system. (Adapted, with permission, from Brandt and Dietrich 1999.)

facilitates the integration of all relevant sensory information for the perception of motion and orientation. In addition, vestibular and visual areas of cortex have reciprocal connections that may be involved in the resolution of contradictory vestibular and visual inputs. For example, motion of an object in the visual field of a person riding in a train or car moving at constant speed is correctly interpreted as self-motion, even though there is no corresponding vestibular signal. An undesired consequence of this is that motion in the visual field is often interpreted as self-motion even when a person is not moving, as when the observer has stopped at a red light and the adjacent vehicle accelerates.

Although the vestibular apparatus measures how one accelerates and tilts, the cerebral cortex employs this information to generate a subjective measure of self-movement in relation to the external world. Otolithic inputs are used by the vestibular cortex to determine the gravitational vertical axis in the visual field. Patients with lesions in this area may perceive themselves or objects in the environment to be tilted away from the side of the lesion. A few patients with parietal lesions perceive their visual environments to be rotated by 90 or 180 degrees.

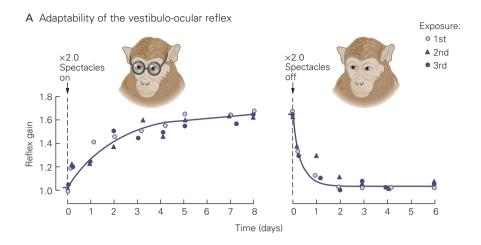

The Cerebellum Adjusts the Vestibulo-Ocular Reflex

As we have seen, the vestibulo-ocular reflex keeps the gaze constant when the head moves. There are times, however, when the reflex is inappropriate. For example, when you turn your head while walking, you want your gaze to follow; the rotational vestibulo-ocular reflex, however, would prevent your eyes from turning with your head. To prevent this sort of biologically inappropriate response, the reflex is under the control of the cerebellum, which permits visual suppression of the vestibulo-ocular reflex.

In addition, the vestibulo-ocular reflex must be continuously calibrated to maintain its accuracy in the face of changes within the motor system (fatigue, injury to vestibular organs or pathways, eye-muscle weakness, or aging) and differing visual requirements (wearing corrective lenses). This is accomplished by sensory feedback that modifies the motor output. If the reflex is not working properly, the image moves across the retina. The motor command to the eye muscles must be adjusted until the gaze is again stable, retinal image motion is zero, and there is no error.

Anyone who wears eyeglasses depends on this plasticity of the vestibulo-ocular reflex. Because lenses for nearsightedness shrink the visual image, a smaller eye rotation is needed to compensate for a given head rotation, and the gain of the vestibulo-ocular reflex must be reduced. Conversely, glasses for farsightedness magnify the image, so the vestibulo-ocular reflex gain must increase during their use. More complicated is the instance of bifocal spectacles, in which the vestibuloocular reflex must use different gains for the two lenses. In the laboratory the vestibulo-ocular reflex can be conditioned by altering the visual consequences of head motion. For example, if a subject is rotated for a period of time while wearing magnifying glasses, the vestibulo-ocular reflex gain gradually increases (Figure 40–14A).

This process requires changes in synaptic transmission in both the cerebellum and the brain stem.

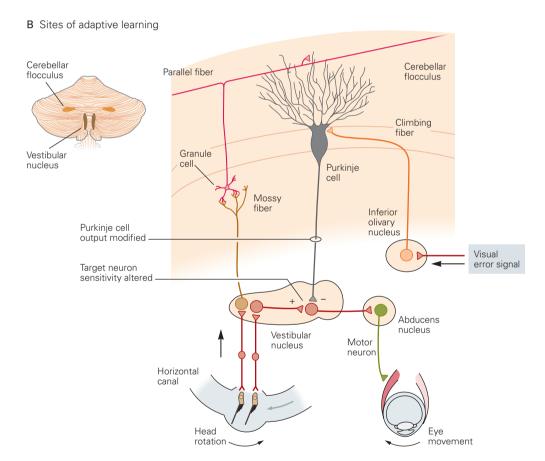

Figure 40–14 The vestibulo-ocular reflex is adaptable.

A. For several days the monkey continuously wears magnifying spectacles that double the speed of the retinal-image motion evoked by head movement. Each day the gain of the vestibulo-ocular reflex—the amount the eyes move for a given head movement—is tested in the dark so that the monkey cannot use retinal motion as a clue to modify the reflex. Over a period of 4 days the gain increases gradually (left). It quickly returns to normal when the spectacles are removed (right). (Adapted, with permission, from Miles and Eighmy 1980.)

B. Adaptation of the vestibulo-ocular reflex occurs in cerebellar and brain stem circuits. A visual error signal, triggered by motion of the retinal image during head movement, reaches the inferior olivary nucleus. The climbing fiber transmits this error signal to the Purkinje cell, affecting the parallel fiber—Purkinje cell synapse. The Purkinje cell transmits changed information to the floccular target cell in the vestibular nucleus, changing its sensitivity to the vestibular input. After the reflex has been adapted, the Purkinje cell input is no longer necessary.

If the flocculus and paraflocculus of the cerebellum are lesioned, the gain of the vestibulo-ocular reflex can no longer be modulated. Mossy fibers carry vestibular, visual, and motor signals from the pontine nuclei to the cerebellar cortex; the granule cells, with their parallelfiber axons, relay these signals to the Purkinje cells (Figure 40-14B). David Marr suggested that the synaptic efficacy of parallel fiber input to a Purkinje cell could be modified by the concurrent action of climbing fiber input. Masao Ito showed that the climbing fiber input to the cerebellum did indeed carry a suitable visual error signal and postulated that this was the "teaching line" enabling the cerebellum to correct the error in the vestibulo-ocular reflex. This adaptation requires long-term depression of the Purkinje cell synapses (see Chapter 42). Transgenic mice lacking long-term synaptic depression in these neurons cannot adapt their vestibulo-ocular reflexes in a few hours, as can normal mice.

The Purkinje cell is not the only locus of change. Frederick Miles and Steven Lisberger showed that there is a class of neurons in the vestibular nucleus, the *flocculus target neurons*, that receive GABA-ergic inhibitory input from Purkinje cells in the flocculus as well as direct inputs from vestibular sensory fibers. During adaptation of the vestibulo-ocular reflex these neurons change their sensitivity to the vestibular inputs in the appropriate way, and after adaptation they can maintain those changes without further input from the cerebellum.

The importance of the cerebellum in calibrating eye movements is also evident in patients with cerebellar disease. Although the vestibulo-ocular reflex is still present, it may have an abnormal amplitude or direction. In many cases the translational vestibulo-ocular reflex is also poor.

Clinical Syndromes Elucidate Normal Vestibular Function

Unilateral Vestibular Hypofunction Causes Pathological Nystagmus

As we have seen, rotation excites hair cells in the semicircular canal whose hair bundles are oriented in the direction of motion and inhibits those whose hair bundles are oriented away from the motion. This imbalance in vestibular signals is responsible for the compensatory eye movements and the sensation of rotation that accompanies head movement. It can also originate from disease of one labyrinth or vestibular nerve, which results in a pattern of afferent vestibular

signaling analogous to that stemming from rotation away from the side of the lesion, that is, more discharge from the intact side. There is accordingly a strong feeling of spinning, called vertigo.

The vestibulo-ocular reflex responds by generating eye movements in an attempt to compensate for this perceived rotation. The slow phases (see Figure 40–8) are directed away from the intact side and toward the lesioned side, and the intervening quick phases produce a nystagmus that beats toward the intact side. For example, an acute loss of left vestibular function causes a right-beating nystagmus, as if there were a prolonged rightward acceleration. Unlike physiological nystagmus, which stabilizes gaze, the pathological nystagmus causes retinal slip and a corresponding sensation that the visual world is moving, called *oscillopsia*.

The vertigo and nystagmus resulting from an acute vestibular lesion typically subside over several days, even if peripheral function does not recover. First, nystagmus can be suppressed by visual fixation, just as post-rotatory nystagmus is suppressed in the light. Second, central compensatory mechanisms restore the balance in vestibular signals in the brain stem, even when peripheral input is permanently lost.

The loss of input from one labyrinth also means that all vestibular reflexes must be driven by a single labyrinth. For the vestibulo-ocular reflex this condition is quite effective at low speeds because the intact labyrinth can be both excited and inhibited. However, during rapid, high-frequency rotations inhibition is not sufficient, such that the gain of the reflex is reduced when the head rotates toward the lesioned side. This is the basis of an important clinical test of canal function, the head-impulse test. In this test the head is moved rapidly one time along the axis of rotation of a single canal. If there is a significant decrease in gain owing to canal dysfunction, the movement of the eyes will lag behind that of the head, and there will be a visible catch-up saccade (Figure 40–15).

Bilateral Vestibular Hypofunction Interferes with Normal Vision

Vestibular function is sometimes lost simultaneously on both sides, for example from ototoxicity owing to aminoglycoside antibiotics such as gentamicin. The symptoms of bilateral vestibular hypofunction are different from those of unilateral loss. First, there is no vertigo because there is no imbalance in vestibular signals; input is reduced equally from both sides. For the same reason there is no spontaneous nystagmus. In fact, these patients may have no symptoms when they are at rest and the head is still.

Subject with damage to left posterior canal

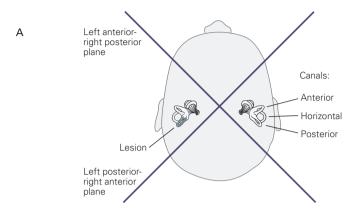

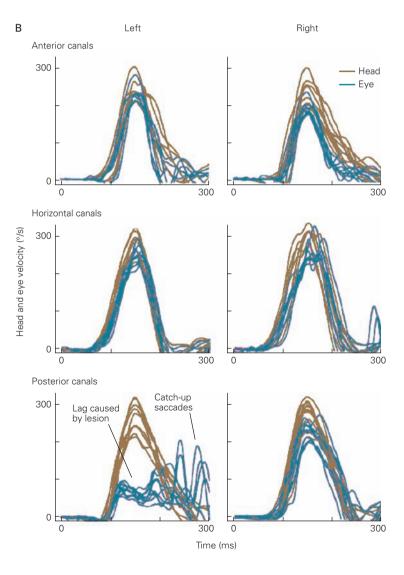

Figure 40–15 Clinical testing of the vestibuloocular reflex.

A. The examiner rotates the patient's head rapidly in the optimum direction for each canal while the subject fixates. This stimulus is termed a *head impulse*. If the canal and oculomotor systems are normal, eye velocity matches head velocity and the eyes maintain gaze—they do not move relative to the external environment. If there is a canal deficit, the eyes lag behind the head and make catch-up saccades after the head movement is finished.

B. The records are the results of impulse testing in a patient with a lesion of the left posterior canal. In the record for the left posterior canal (rotation in the left posterior–right anterior plane), eye velocity fails to track the head velocity during the most rapid parts of the head movement. After the head movement is over, pulses of eye velocity correspond to the catchup saccades induced by the visual error.

Nevertheless, the loss of vestibular reflexes is devastating. A physician who lost his vestibular hair cells because of a toxic reaction to streptomycin wrote a dramatic account of this loss. Immediately after the onset of streptomycin toxicity he could not read in bed without steadying his head to keep it motionless. Even after partial recovery he could not read street signs or recognize friends while walking in the street; he had to stop to see clearly. Some patients may even "see" their heartbeat if the vestibulo-ocular reflex fails to compensate for the miniscule head movements that accompany each arterial pulse.

An Overall View

The vestibular system evolved to answer two of the questions basic to human life: "Which way is up?" and "Where am I going?" The system provides the brain with a rapid estimate of head motion. Although this estimate could be derived from vision and neck proprioception, those sensory mechanisms are slow and cumbersome. In contrast, the hair cells of the vestibular system sense head acceleration directly, and this responsiveness in turn allows those reflexes that require information about head motion to act efficiently and quickly.

There are two distinct sets of vestibular organs. The three semicircular canals sense head rotation, whereas the otolith organs—the utricle and saccule—detect linear acceleration. Signals from the canals and otolith organs are carried in the vestibular nerve to the ipsilateral vestibular nuclei.

Projections from the vestibular nuclei to the oculomotor system allow eye muscles to compensate for head movement by moving in such a way as to hold the image of the external world motionless on the retina. Sustained rotation results in a pattern of alternating slow and fast eye movements called nystagmus. The slow eye movement is equal and opposite to the head movement, whereas the fast eye movement represents a resetting movement in the opposite direction. Nystagmus in the absence of sustained head rotation is a sign of disease of the vestibular apparatus or its central connections. Vestibular signals habituate during sustained rotation and are relatively insensitive to very slow head movements.

Head movement evokes motion of the entire visual image on the retina as the moving eyes sweep across a stable visual field. This visual signal supplements the vestibular signal in the brain and compensates for the tendency of the vestibular signal to adapt during prolonged rotation. The optokinetic system

provides the visual input to the central vestibular system. The motion of the retinal image induced by head movement enables the optokinetic system to induce eye movements and perceptions that are equivalent to those induced by actual head movement.

The vestibulo-ocular reflex is adaptable. If a process such as muscle weakness or visual distortion alters the relationship between the visual input and the motor output, the brain compensates for that change. This compensation requires activity in both the cerebellum and the vestibular nuclei.

Posture

Postural Equilibrium and Orientation Are Distinct Sensorimotor Processes

Postural Equilibrium Requires Control of the Body's Center of Mass

Balance During Stance Requires Muscle Activation

Automatic Postural Responses Counteract Unexpected Disturbances

Automatic Postural Responses Adapt to Changes in the Requirements for Support

Anticipatory Postural Adjustments Compensate for Voluntary Movements

Postural Orientation Is Important for Optimizing Execution of Tasks, Interpreting Sensations, and Anticipating Disturbances to Balance

Sensory Information from Several Modalities Must Be Integrated to Maintain Equilibrium and Orientation

Somatosensory Afferents Are Important for Timing and Direction of Automatic Postural Responses

Vestibular Information Is Important for Balance on Unstable Surfaces and During Head Movements

Visual Information Provides Advance Knowledge of Potentially Destabilizing Situations and Assists in Orienting to the Environment

Information from a Single Sensory Modality Can Be Ambiguous

The Postural Control System Uses a Body Schema that Incorporates Internal Models for Balance

The Influence of Each Sensory Modality on Balance and Orientation Changes According to Task Requirements

Control of Posture Is Distributed in the Nervous System

Spinal Cord Circuits Are Sufficient for Maintaining Antigravity Support but Not Balance

The Brain Stem and Cerebellum Integrate Sensory Signals for Posture

The Spinocerebellum and Basal Ganglia Are Important in Adaptation of Posture

Cerebral Cortex Centers Contribute to Postural Control

An Overall View

THE CONTROL OF POSTURE IS CRUCIAL for most tasks of daily living. The two components of posture, orientation and balance, require continual adjustment and involve several sensory systems.

To appreciate the complexity of maintaining balance and orientation, imagine that you are waiting tables on a tour boat. You have a tray full of drinks to be delivered to a table on the other side of the rolling deck. Even as your mind is occupied with remembering customer orders, unconscious processes allow you to move about in a smooth and coordinated manner.

The apparently simple task of delivering drinks is supported by a truly complex sensorimotor process for controlling postural orientation and balance. As you cross the deck your brain rapidly processes sensory information and adjusts motor output to maintain your balance, the upright orientation of your head and trunk, and stable arms supporting the tray of full glasses. Before you reach out to place a glass on the table, your nervous system makes anticipatory postural adjustments to maintain your balance. Sudden unexpected motions of the boat evoke automatic postural responses that prevent falls. Somatosensory, vestibular, and visual information is integrated to provide a coherent picture of the position and velocity of the

body in space and to generate and update motor commands that maintain balance and orientation.

Postural Equilibrium and Orientation Are Distinct Sensorimotor Processes

Postural equilibrium, or balance, involves active resistance to external forces acting on the body. The dominant external force affecting equilibrium on earth is gravity. Postural orientation is the positioning of body segments with respect to each other and to the environment. Depending on the particular task or behavior, body segments may be aligned with respect to gravitational vertical, visual vertical, or the support surface.

The biomechanical requirements of postural control depend on anatomy and postural orientation and thus vary with the animal. Nevertheless, in a variety of species the control mechanisms for postural equilibrium and orientation have many common features. The sensorimotor mechanisms for postural control are quite similar in humans and quadrupedal mammals even though their habitual stance is different.

Postural Equilibrium Requires Control of the Body's Center of Mass

With many segments linked by joints, the body is mechanically unstable. To maintain balance the nervous system must control the position and motion of the body's *center of mass* as well as the body's rotation about its center of mass. The center of mass is a point that represents the average position of the body's total mass. In the standing cat, for example, the center of mass is located in the trunk just rostral to the midpoint between forelimbs and hind limbs.

Although gravity pulls on all body segments, the net effect on the body acts through the center of mass. The force of gravity is opposed by the *ground reaction force*, which pushes upward against each foot. The net ground reaction force occurs at an imaginary point on the ground called the *center of pressure* (Box 41–1).

The location of the center of mass in the body is not fixed but depends on postural orientation. When you are standing upright, for example, your center of mass is located in the abdomen approximately 20 mm in front of the second lumbar vertebra. When you flex at the hips, however, the center of mass moves forward to a position outside the body.

Maintaining balance while standing requires keeping the downward projection of the center of mass within the base of support, an imaginary area defined by those parts of the body in contact with the environment.

For example, the four paws of a standing cat define a rectangular base of support (see Figure 41–1). When a standing person leans against a wall, the base of support extends from the ground under the feet to the contact point between the body and the wall. Because the body is always in motion, even during stable stance, the center of mass continually moves about with respect to the base of support. Postural instability is determined by how fast the center of mass is moving toward the boundary of its base of support and how close the downward projection of the body's center of mass is to the boundary.

Balance During Stance Requires Muscle Activation

Upright stance requires two actions: (1) maintaining support against gravity (keeping the center of mass at some height) and (2) maintaining balance (controlling the trajectory of the center of mass in the horizontal plane). Balance and antigravity support are controlled separately by the nervous system and may be differentially affected in certain pathological conditions.

Antigravity support, or postural tone, represents the tonic activation of muscles that generate force against the ground to keep the limbs extended and the center of mass at the appropriate height. A cat stands with its limbs in a semiflexed posture (see Figure 41–1) and its extensor muscles are tonically activated to prevent the joints from collapsing into flexion. In humans much of the support against gravity is provided by passive bone-on-bone forces in joints such as the knees, which are fully extended during stance, and in stretched ligaments such as those at the front of the hips. Nevertheless, antigravity support in humans also requires active muscle contraction, for example in ankle, trunk, and neck extensors. Tonic activation of antigravity muscles is not sufficient, however, for maintaining balance.

Both bipeds and quadrupeds are inherently unstable, and their bodies sway during quiet stance. Actively contracting muscles exhibit a spring-like stiffness that helps to resist body sway, but muscle stiffness alone is insufficient for maintaining balance. Likewise, stiffening of the limbs through muscle co-contraction is not sufficient for balance control. Instead, complex patterns of muscle activation produce direction-specific forces to control the body's center of mass. Body sway caused by even subtle movements, such as the motion of the chest during breathing, is actively counteracted by the posture control system.

Automatic Postural Responses Counteract Unexpected Disturbances

When a sudden disturbance causes the body to sway, various motor strategies are used to maintain the center

Box 41–1 Center of Pressure

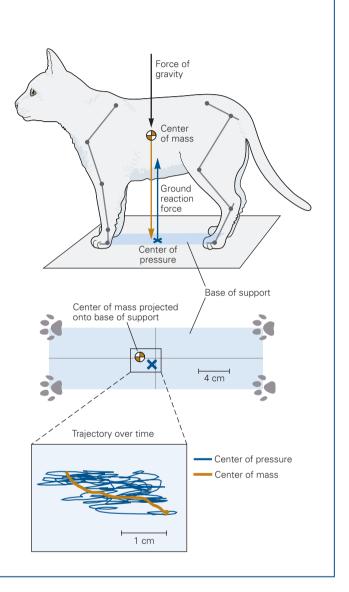

The center of pressure is defined as the origin of the ground reaction force vector on the support surface. For the body to be in static equilibrium, the force caused by gravity and the ground reaction force must be equal and opposite, and the center of pressure must be directly under the center of mass.

Misalignment of the center of pressure and center of mass causes motion of the center of mass. If the center of pressure is behind and to the left of the center of mass projection onto the base of support, for example, the body will sway forward and to the right (Figure 41–1).

When no external forces other than gravity are present, the center of pressure and ground reaction force reflect the net effect of muscles activated by the postural system to actively control the center of mass position and therefore balance.

Standing is never truly static. The center of pressure and center of mass are continually in motion and are rarely aligned, although when averaged over time during quiet stance they are coincident. The actual sway of the body during quiet stance is described by the trajectory of the center of mass, not the center of pressure.

Figure 41–1 The center of mass moves during stance but remains within the base of support. The base of support of the standing cat is defined by the points of contact of the paws on the support surface. The force caused by gravity passes through the center of mass in the trunk. The surface exerts an upward force against each paw, such that the ground reaction force vector originates in the center of pressure on the support surface. Although the paws remain in place, the centers of pressure and mass are always in motion as the cat sways.

of mass within the base of support. In one strategy the base of support remains fixed relative to the support surface. While the feet remain in place the body rotates about the ankles back to the upright position (Figure 41–2A). In other strategies the base of support is moved or enlarged, for example by taking a step or by grabbing a support with the hand (Figure 41–2B).

Older views of motor control focused on trunk and proximal limb muscles as the main postural effectors. Recent behavioral studies show that any group of muscles from the neck and trunk, legs and arms, or feet and hands can act as postural muscles depending on the body parts in contact with the environment and the biomechanical requirements of equilibrium.

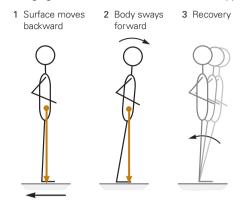

When studying the posture control system, scientists disrupt balance in a controlled manner to determine the subject's automatic postural response. This response is described by the ground reaction force vector under each foot, the motion of the center of pressure, and the movements of the body segments. The electrical activity of many muscles is recorded by electromyography (EMG), which reflects the firing of alpha

Figure 41–2 Automatic postural responses keep the downward projection of the center of mass within the boundaries of the base of support.

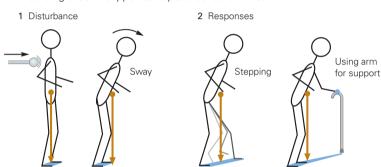

A. One strategy for regaining balance is to bring the center of mass back to its origin on the base of support. When the platform on which a subject is standing is suddenly moved backward, the body sways forward and the projection of the center of mass moves toward the toes. During recovery the body actively rotates about the ankles, bringing the center of mass back to the original position with respect to the feet.

B. An alternative strategy enlarges the base of support to keep the center of mass within the base. A disturbance causes the subject to sway forward and the center of mass moves toward the boundary of the base of support. The base can be enlarged in two ways: taking a step and placing the foot in front of the center of mass to decelerate the body's motion, or grabbing a support and thereby extending the base to include the contact point between the hand and support.

A Bringing center of mass back over base of support

B Extending base of support to capture center of mass

motor neurons that innervate skeletal muscle and thus provides a window into the nervous system's output for balance control. The combination of all these measurements allows investigators to infer the active neural processes underlying balance control.

An automatic postural response to a sudden disturbance is not a simple reflex but rather the synergistic activation of a group of muscles in a characteristic sequence with the goal of maintaining equilibrium. The recruitment of a muscle during a postural response reflects the requirements of equilibrium rather than the change in the muscle's length caused by the disturbance. For example, when the surface under a person is rotated in the toes-up direction, the ankle extensor (gastrocnemius) is lengthened and a small stretch reflex may occur. The postural response for balance recruits the antagonist ankle flexor (tibialis anterior), which itself is shortened by the surface rotation, while suppressing the stretch response in the gastrocnemius. In contrast, when the platform is moved backward the gastrocnemius is again lengthened but now it is recruited for the postural response, as evidenced by a second burst of EMG activity after the stretch reflex. Thus the initial change in length of a muscle induced by perturbation does not determine whether that muscle is recruited for postural control, and stretch reflexes are not the basis for postural control.

Automatic postural responses to sudden disturbances have characteristic temporal and spatial features. A postural response in muscles must be recruited rapidly following the onset of a disturbance. Sudden movement of the support surface under a standing cat evokes EMG activity within 40–60 ms (Figure 41–3). Humans have longer latencies of postural response (80–120 ms); the increased delay is attributed to the larger body size of humans and thus the greater signal conduction distances from sensory receptors to the central nervous system and thence to leg muscles. The latency of automatic postural responses is shorter than voluntary reaction time but longer than the stretch reflex.

Postural responses involving a change in support base, such as stepping, have longer latencies than those that occur when the feet remain in place.

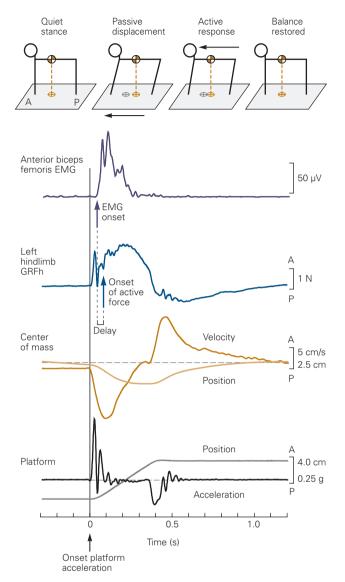

Figure 41-3 Automatic postural responses have stereotypical temporal characteristics. Electromyographic (EMG) activity has a characteristic latency. Anterior motion of the platform evokes an EMG response in the hip extensor muscle (anterior biceps femoris) approximately 40 ms after the onset of platform acceleration. This latency is stereotyped and repeatable across subjects and is approximately four times as long as that of the monosynaptic stretch reflex. As the platform moves, the paws are carried forward and the trunk remains behind owing to inertia, causing the center of mass of the cat to move backward with increasing velocity with respect to the platform. The velocity of the center of mass peaks and then decreases as the horizontal component of the ground reaction force (GRFh) increases following muscle activation. The delay of approximately 30 ms between the onset of EMG activity and the onset of the active response reflects excitation-contraction coupling and body compliance. The automatic postural response extends the hind limb, propelling the trunk forward and restoring the position of the center of mass with respect to the paws.

The longer time presumably affords greater flexibility in the response, for example the choice of foot to begin the step, the direction of the step, and the path of the step around obstacles.

Activation of postural muscles results in contraction and the development of force in the muscles, leading to torque (rotational force) at the joints. The net result is an active response, the ground reaction force, that restores the center of mass to its original position over the base of support (Figure 41–3). The delay between EMG activation and the active response, approximately 30 ms in the cat, reflects the excitation-contraction coupling time of each muscle as well as the compliance of the musculoskeletal system.

The amplitude of EMG activity in a particular muscle depends on both the speed and direction of postural disturbance. The amplitude increases as the speed of a platform under a standing human or cat increases, and it varies in a monotonic fashion as the direction of platform motion is varied systematically. Each muscle responds to a limited set of perturbation directions with a characteristic tuning curve (Figure 41–4).

Although individual muscles have unique directional tuning curves, muscles are not activated independently but instead are coactivated in synergies. The muscles within a synergy receive a common command signal during postural responses. In this way the many muscles of the body are controlled by just a few signals, reducing the time needed to compute the appropriate postural response (Box 41–2).

Automatic Postural Responses Adapt to Changes in the Requirements for Support

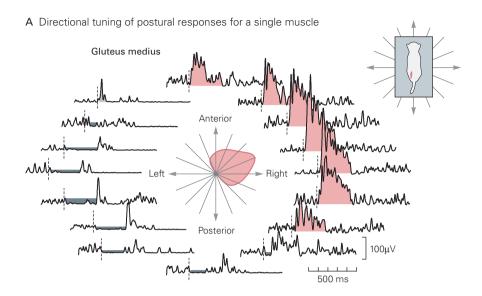

The set of muscles recruited in a postural response to a disturbance depends on the body's initial stance. The same disturbance elicits very different postural responses in someone standing unaided, standing while grasping a stable support, or crouching on all four limbs. For example, forward sway activates muscles at the back of the legs and trunk during upright free stance. When the subject is holding onto a stable support, muscles of the arms rather than those of the legs are activated. When the subject is crouched on toes and fingers, muscles at the front of the legs and in the arms are activated (Figure 41–6A).

Because postural responses are influenced by recent experience, they adapt only gradually to new biomechanical conditions. When forward sway is induced by backward motion of a platform on which a subject is standing, the posterior muscles of the ankle, knee, and hip are activated in sequence beginning

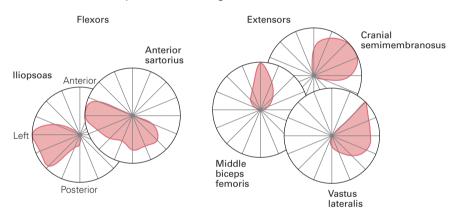

Figure 41–4 Automatic postural responses have stereotypical directional characteristics. (Adapted, with permission, from Macpherson 1988.)

A. The gluteus medius muscle in the cat, a hip extensor and abductor. responds to a range of directions of motion in the horizontal plane. The EMG records shown here are from a cat standing on a platform that was moved in the horizontal plane in each of 16 evenly spaced directions. The gluteus medius muscle of the left hind limb was activated by motion in several directions (pink) and inhibited in the remaining directions (gray). The dashed vertical lines indicate the onset of platform acceleration. In the center is a polar plot of the amplitude of EMG activity during the automatic postural response versus the direction of motion; it represents a directional tuning curve for the muscle. EMG amplitude was computed from the area under the curve during the first 80 ms of the response.

B. Every muscle has a characteristic directional tuning curve that differs from that of other muscles, even if they have similar actions. The middle biceps femoris and cranial semimembranosus, for example, are both extensors of the hip.

B Each muscle has unique directional tuning

90 ms after the platform starts moving. This postural response, the *ankle strategy*, restores balance primarily by rotating the body about the ankle joints. However, when forward sway is induced by backward motion of a narrow beam, the anterior muscles of the hip and trunk are activated. This postural pattern, the *hip strategy*, restores the body's center of mass by bending forward at the hip joints and counter-rotating at the ankles (Figure 41–6B).

When a subject moves from the wide platform to the narrow beam, he persists in using the ankle strategy in the first few trials. This strategy does not work when standing on the beam, and the subject falls. He then gradually, over several trials, switches to the hip strategy. Similarly, moving from the beam back to the platform requires several trials to adapt the postural response (Figure 41–6C).

Although sensory stimulation changes immediately after subjects move from the beam to the floor, the postural response adjusts gradually as it is tuned for optimal behavior by trial and error. Trial-to-trial changes in postural behavior generally occur at the subconscious level and involve updating of the body schema.

Anticipatory Postural Adjustments Compensate for Voluntary Movements

Voluntary movements themselves can destabilize postural orientation and equilibrium. Rapidly lifting the arms forward while standing, for example, produces forces that extend the hips, flex the knees, and dorsiflex the ankles, moving the body's center of mass forward relative to the feet. The nervous system has advance

knowledge of the effects of voluntary movement on postural alignment and stability and activates *anticipatory postural adjustments*, often in advance of the primary movement (Figure 41–7A).

Anticipatory postural adjustments are specific to biomechanical conditions. When a freely standing subject rapidly pulls on a handle fixed to the wall, the leg muscles (gastrocnemius and hamstrings) are activated before the arm muscles (Figure 41–7B). When the subject performs the same pull while his shoulders are propped against a rigid bar, no anticipatory leg muscle activity occurs because the nervous system relies on the support of the bar to prevent the body from moving forward. When the handle is pulled in response to an external cue, the arm muscles are activated faster in the supported condition than in the freestanding condition. Thus voluntary arm muscle activation is normally delayed when the task requires active postural stability.

Another common preparatory postural adjustment occurs when one begins to walk. The center of mass is accelerated forward and laterally by the unweighting of one leg. This postural adjustment appears to be independent of the stepping program that underlies ongoing locomotion. Similarly, a forward shift of the center of mass precedes the act of standing on the toes. A subject is unable to remain standing on his toes if he simply activates the calf muscles without moving his center of mass forward; he rises onto his toes only momentarily before gravity restores a flat-footed stance. Moving the center of mass forward over the toes before activating the calf muscles aligns it over the anticipated base of support and thus stabilizes the toe stance.

Locomotion, too, has an important postural component. During walking and running the body is in a constant state of falling as the center of mass moves forward and laterally toward the leg that is in the swing phase. The center of mass is within the base of support during walking only when both feet are on the ground, the double stance phase, and not at all during running. When one foot is supporting the body, the center of mass moves forward in front of the foot, always medial to the base of support. Falling is prevented during walking and running by moving the base of support forward and laterally under the falling center of mass. Postural equilibrium during gait relies on the appropriate placement of each step to control the speed and trajectory of the center of mass (Figure 41–7C). The nervous system plans foot placement several steps in advance using visual information about the terrain and surrounding environment (see Chapter 36).

Postural equilibrium during voluntary movement requires control not only of the position and motion

of the body's center of mass but also of the angular momentum about the center of mass. A diver can perform elaborate rolls and twists of the body about the center of mass while airborne although the trajectory of his center of mass is fixed once he leaves the board. During swimming and flying the water or air currents in addition to the body's own movements may cause the body to pitch or roll about the center of mass. During voluntary movements postural adjustments control the body's angular momentum by anticipating rotational forces.

Postural Orientation Is Important for Optimizing Execution of Tasks, Interpreting Sensations, and Anticipating Disturbances to Balance

Animals arrange their body parts to accomplish specific tasks efficiently. Although this postural orientation interacts with balance control, the two systems can act independently.

The energy needed to maintain body position over a period of time can influence postural orientation. In humans, for example, the upright orientation of the trunk with respect to gravity minimizes the forces and thus the energy required to hold the body's center of mass over the base of support. Standing cats adopt a characteristic distance between front and back paws that minimizes the energy needed for remaining upright.

Task requirements also affect postural orientation. For some tasks it is important to stabilize the position of a body part in space, whereas for others it is necessary to stabilize one body part with respect to another. When walking while carrying a full glass, for example, it is important to stabilize the hand against gravity to prevent spillage. When walking while reading a book, the hand must be stabilized with respect to the head and eyes.

Subjects may adopt a particular postural orientation to optimize the accuracy of sensory signals regarding body motion, especially while on unstable or moving surfaces. In activities such as skiing and windsurfing, in which the substrate is unstable, information about earth vertical is derived primarily from vestibular and visual inputs. A person often aligns his head with respect to gravitational vertical because the perception of vertical is most accurate in this position and decreases in accuracy as the head is tilted. The vestibular and visual information regarding the external world, representing an extrinsic coordinate system,

Box 41–2 Synergistic Activation of Muscles

Coordinated movements require precise control of the many joints and muscles in the body. Maintaining control is biomechanically complex, in part because different combinations of joint rotations can achieve the same goal. Such redundancy confers great flexibility, for example in modifying stepping patterns to negotiate obstacles in our path, but comes at the cost of increased complexity in the brain's computation of movement trajectories and forces.

Many factors must be included in the computation of movement commands, including the effect of external forces such as gravity and the forces that one body segment exerts on another during motion. All these factors come into play when the brain computes postural responses to sudden disturbances, but with the added constraint of a time limit on computation: Responses must occur within a certain time or balance will be lost.

It has long been believed that the brain simplifies the control of movement by grouping control variables, for example activating several muscles together. In older concepts of synergy the same muscles are always recruited together. This kind of synergy cannot apply to balance responses because each muscle has a unique directional tuning curve and the tuning curves overlap imperfectly (see Figure 41–4B).

Using mathematical techniques that parse complex data into a small number of components, Lena Ting and Jane Macpherson showed that only four or five synergies are needed to account for the activation patterns of 15 hind limb muscles of the cat during automatic postural responses to many directions of platform motion (Figure 41–5). Activation of each synergy produces a unique direction of force against the ground, suggesting that postural control is based on task-related variables such as the force between foot and ground rather than the contraction force of individual muscles.

Like the arrangement of notes in a musical chord, each muscle synergy specifies how a particular muscle should be activated together with others. Just as one note belongs to several different chords, each muscle belongs to more than one synergy. When several chords are played simultaneously, the chord structure is no longer evident in the multitude of notes. Similarly, when several synergies are activated concurrently, the observed muscle pattern gives the appearance of unstructured complexity. Concurrent activation of synergies nevertheless simplifies the neural command signals for movement while allowing flexibility and adaptability.

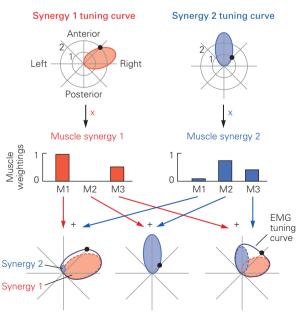

Figure 41–5 Postural commands activate synergies rather than individual muscles.

A. The flow chart illustrates two hypothetical synergies that are recruited during the postural response to one direction of translation in the horizontal plane. A posture controller computes the appropriate force vector response for restoring center of mass position and then specifies how much to activate each synergy. Each muscle synergy activates the muscles in a fixed proportion. The height of each bar represents the relative amount of activation, or weighting, for each muscle M1 to M3. Synergy 1 produces a downward force vector by activating M1 strongly, M2 not at all, and M3 moderately. Synergy 2 produces a downward and posterior force vector using the same muscles but with different levels of activation: M1 slightly, M2 strongly, and M3 moderately. When synergy 1 is activated with an amplitude of 2 and synergy 2 an amplitude of 1, the desired force vector response is achieved. Signals from the two muscle synergies are summated in the population of motor neurons innervating each muscle. The contribution of each synergy to the total electromyogram (EMG) activation can be determined.

B. The two hypothetical synergies in part A can generate the unique tuning curves for muscles M1 to M3 in response to all 16 directions of translation in the horizontal plane. The posture controller generates a command signal to each synergy that is tuned to direction of translation (synergy tuning curves). Muscle synergy weightings are multiplied by the synergy amplitudes. Signals from the two synergies are summated at the motor neurons, resulting in EMG activity that is tuned to a direction (the EMG tuning curve). The tuning curve for each of the three muscles is different even though only two synergy commands are used. The contribution of each synergy to the EMG tuning curve of a muscle can also be determined. The black dots indicate the amplitudes of the two synergies and resulting EMG activity of the three muscles for the direction illustrated in part A.

B Directional tuning of synergies

is integrated with proprioceptive information, representing an intrinsic coordinate system, to determine the position of the body in space (see Chapter 38). The accuracy of the transformation from intrinsic to extrinsic coordinates may be enhanced if at least one sensory input is aligned with the extrinsic system.

Anticipatory alterations of habitual body orientation can minimize the effect of a possible disturbance. For example, people often lean in the direction of an anticipated external force, or they flex their knees, widen their stance, and extend their arms when anticipating that surface stability will be compromised.

Sensory Information from Several Modalities Must Be Integrated to Maintain Equilibrium and Orientation

Information about motion from any one sensory system may be ambiguous. Thus multiple sources of sensory information must be integrated in postural centers to determine what orientation and motion of the body in space are appropriate. The influence of any one modality on the postural control system varies according to the task and biomechanical conditions.

According to the prevailing theory, sensory modalities are integrated to form an internal representation of the body that the nervous system uses to plan and execute motor behaviors. Over time this internal representation must adapt to changes associated with early development, aging, and injury.

Somatosensory Afferents Are Important for Timing and Direction of Automatic Postural Responses

Large-diameter, fast somatosensory fibers are critical for maintaining balance during stance. When these axons die, as occurs in some forms of peripheral neuropathy, postural responses to movement of the support surface are delayed, retarding the ground reaction force. As a result, the center of mass moves faster and farther from the initial position and takes longer to return (Figure 41–8). Because it is more likely that the center of mass will move outside the base of support, balance is precarious and a fall may occur. Individuals with large-fiber peripheral neuropathy in the legs accordingly experience ataxia and difficulties with balance.

The somatosensory fibers that give rise to the automatic postural response have not been identified. The largest fibers, those in group I (12–20 µm in diameter), appear to be essential for normal response latencies.

A Stance determines postural response

B Platform width affects postural response

C Adaptation of postural response

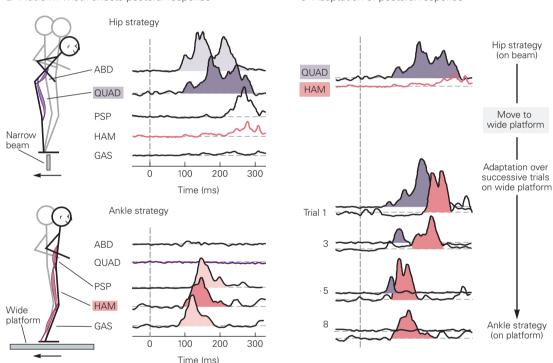

Figure 41–6 Automatic postural responses change with biomechanical conditions.

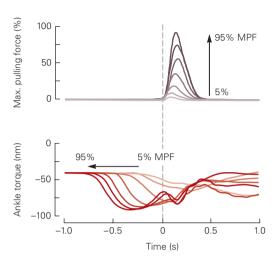

A. The backward movement of a platform activates different groups of muscles depending on initial stance. Gray stick figures show initial positions (upright unsupported, quadrupedal, or upright supported). The muscles activated in each postural response are shown in red. (Adapted, with permission, from Dunbar et al. 1986.)

B. When a subject stands on a narrow beam that is abruptly moved backward, the anterior muscles—abdominals (ABD) and quadriceps (QUAD)—are recruited to flex the trunk and extend the ankles, moving the hips backward (the hip strategy). When the subject instead stands on a wide platform that is moved backward, his posterior muscles—paraspinals (PSP), hamstrings (HAM), and gastrocnemius (GAS)—are activated

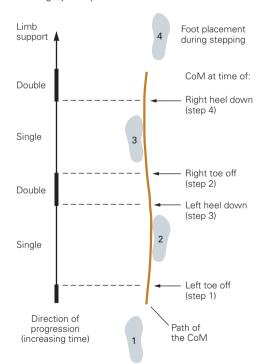

to bring the body back to the erect position by rotating at the ankles (the ankle strategy). Muscles representative of different postural responses are highlighted in color. **Dashed vertical line** indicates onset of platform (or beam) acceleration.

C. Postural strategy adapts after the subject moves from the narrow beam onto the wide platform. On the beam the quadriceps are activated and the hamstrings are silent; after adaptation to the wide platform the reverse is observed. The transition from quadriceps to hamstrings occurs over a series of trials; the quadriceps activity gradually decreases in amplitude, whereas the hamstrings are activated earlier and earlier, until by trial eight quadriceps activity disappears altogether. Ankle and trunk muscles show similar patterns of adaptation. (Adapted, with permission, from Horak and Nashner 1986.)

A Ankle force precedes pulling force during voluntary arm pull

C Center of mass position is controlled during walking by foot placement

B Postural muscles are recruited only when needed

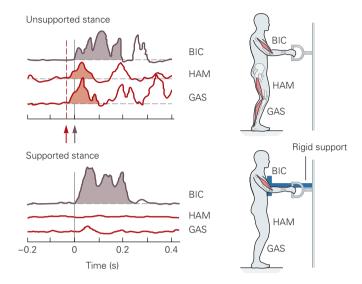

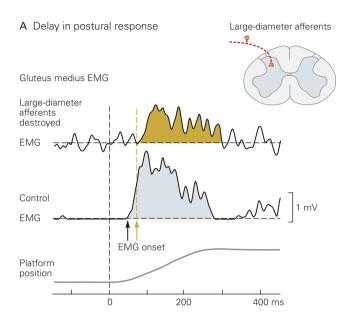

Figure 41–7 Anticipatory postural adjustments precede voluntary movement.

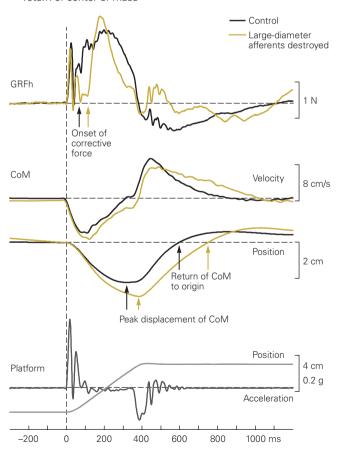

A. The postural component of a voluntary arm pull increases in amplitude and lead time as the pulling force increases. In this experiment subjects were asked to pull on a handle attached to the wall by a wire. Subjects stood on a force plate and, at a signal, pulled rapidly on the handle to reach a specified peak force varying between 5% and 95% of maximum pulling force. Each pull was preceded by leg-muscle activation that produced a rotational force, or torque, about the ankle joints. The larger the pulling force, the larger and earlier was the ankle torque. Traces are aligned at the onset of the pulling force on the handle at time zero. (MPF, maximum pulling force.) (Adapted, with permission, from Lee, Michaels, and Pai 1990.)

B. Postural adjustments accompany voluntary movement only when needed. As in part A subjects were asked to pull on a handle fixed to a wall. Electromyogram (EMG) traces are aligned at time zero, the onset of activity in the arm muscle, biceps brachii (BIC). During unsupported stance the leg muscles—hamstrings (HAM) and gastrocnemius (GAS)—are activated prior to the arm muscle to prevent the body from rotating forward during the arm pull. The red arrow shows the onset of gastrocnemius activation, the brown arrow that of the biceps brachii. When the subject was supported by a rigid bar at the shoulder, the leg muscle activity was not necessary because the body could not rotate forward. Shaded areas indicate anticipatory postural responses and the initial arm muscle activation. (Adapted, with permission, from Cordo and Nashner 1982.)

C. During walking the trajectory of the center of mass (CoM) is controlled by foot placement. The body's center of mass is between the feet, moving forward and from side to side as the subject walks forward. When the body is supported by only one leg, the center of mass is outside the base of support and moves toward the lifting limb. People do not fall while walking because the placement of the foot on the next step decelerates the center of mass and propels it back toward the midline. (Adapted, with permission, from MacKinnon and Winter 1993.)

B Delay in development of force at the ground and return of center of mass

The largest and most rapidly conducting sensory fibers are the Ia afferents from muscle spindles and Ib afferents from Golgi tendon organs as well as some fibers from cutaneous mechanoreceptors (see Chapter 22). Group I fibers provide rapid information about the biomechanics of the body including responses to muscle stretch, muscle force, and directionally specific pressure on the foot soles. Although group II fibers from muscle spindles and cutaneous receptors may also play a role in shaping automatic postural responses, they may be too slow to generate the earliest part of the response.

Lena Ting and co-workers showed that the temporal features of postural EMG in both quadrupeds and bipeds could be explained by a linear combination of position, velocity, and acceleration of the body's center of mass with a time delay. This suggests that information about the displacement of the center of mass is used in a feedback manner to sculpt the activation of postural muscles over time. According to this model the longer latency, slower rise time, and lower amplitude of the EMG response following destruction of group I fibers reflect a loss of acceleration information such as that encoded by muscle spindle primary receptors (Figure 41–8A). Thus center of mass acceleration may be signaled mainly by group I somatosensory fibers and center of mass velocity and position in part by the slower group II fibers.

Both proprioceptive and cutaneous inputs provide cues about postural orientation. During upright stance, for example, muscles lengthen and shorten as the body sways under the force of gravity, generating proprioceptive signals related to load, muscle length,

Figure 41–8 Loss of large-diameter somatosensory fibers delays automatic postural responses. Electromyograms EMG of postural responses to horizontal motion were recorded in a cat before and after destruction of the large-diameter (group I) somatosensory fibers throughout the body by vitamin B6 intoxication. Motor neurons and muscle strength are not affected by the loss of the somatosensory fibers, but afferent information about muscle length and force is diminished. (Reproduced, with permission, from J. Macpherson.)

A. The postural response in the gluteus medius evoked by horizontal motion of the support platform is significantly delayed after B6 intoxication. This delay of approximately 20 ms induces ataxia and difficulty in maintaining balance.

B. Destruction of group I fibers delays activation of the hind limb. This delay slows the restoration of the center of mass (**CoM**) and the recovery of balance following platform displacement. The delay in onset of the horizontal component of the ground reaction force (**GRFh**) results in a greater peak displacement of the center of mass and a delay in return of the center of mass to its origin relative to the paws.

and velocity of stretch. Joint receptors may detect compressive forces on the joints, whereas cutaneous receptors in the sole of the foot respond to motion of the center of pressure and to changes in ground reaction force angle as the body sways. Pressure receptors near the kidneys may be sensitive to gravity and used by the nervous system to help detect upright or tilted postures. All of these signals contribute to the neural map of the position of body segments with respect to each other and the support surface, and may contribute to the neural computation of center of mass motion.

Vestibular Information Is Important for Balance on Unstable Surfaces and During Head Movements

The otolithic organs of the vestibular apparatus provide information about the direction of gravity, whereas the semicircular canals measure the velocity of head rotation (see Chapter 40). Vestibular information can therefore inform the nervous system about how much the

body is tilted with respect to gravity as well as whether it is swaying forward, backward, or sideways.

Somatosensory and vestibular information about the gravitational angle of the body is combined to orient the body with respect to gravity and other inertial forces. To maintain balance while riding a bike in a circular path at high speed, for example, the body and bike must be oriented with respect to a combination of gravitational and centripetal forces (Figure 41–9A).

Unlike somatosensory inputs, vestibular signals are not essential for the normal timing of balance reactions. Instead they influence the directional tuning of a postural response by providing information about the orientation of the body relative to gravity. In humans and experimental animals lacking vestibular signals, the postural response to *angular* motion or tilt of the support surface is opposite to the normal response. Instead of resisting the tilt, subjects lacking vestibular signals actively push themselves downhill (Figure 41–10). In contrast, the response to *linear*

A Orienting to gravito-inertial force

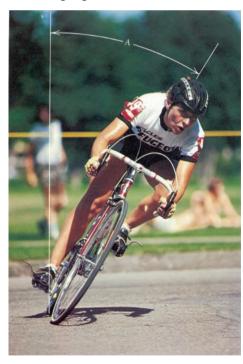

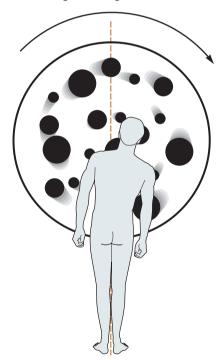

Figure 41–9 The postural system orients the body to various external reference frames.

A. When traveling at high speed along a curved path a cyclist orients to the gravito-inertial force (angle A), the vector sum of the force caused by gravity and the centripetal force caused by acceleration along the curved path. (Reproduced, with permission, from McMahon and Bonner 1983.)

B Orienting to rotating visual field

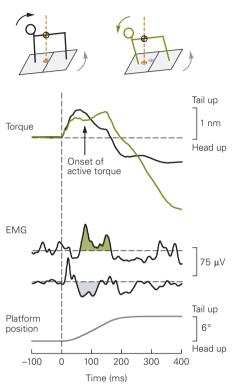

B. The postural system can interpret rightward rotation of objects occupying a large region of the visual field as the body tilting to the left. In compensation for this illusion of motion the subject tilts to the right, adopting a new postural vertical that is driven by the visual system. Gravitational vertical is indicated by the **red dashed line**. (Adapted, with permission, from Brandt, Paulus, and Straube 1986.)

A Tilt

1 Postural response is opposite to control

2 Directional tuning of muscle is opposite to control

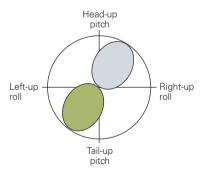

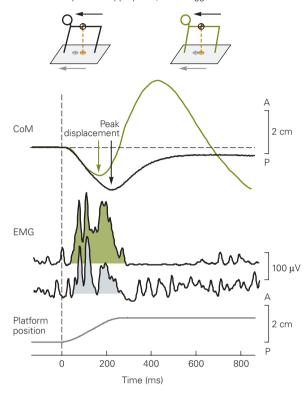

Figure 41–10 Loss of vestibular input disrupts the directional tuning of the automatic postural response to tilt of the support surface. The electromyogram (EMG) records are from cats standing on a movable platform before and after bilateral labyrinthectomy. (Adapted, with permission, from Macpherson et al. 2007.)

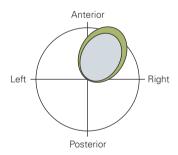

A. Without vestibular inputs the postural response to tilt of the platform is opposite to normal. 1. The lateral gastrocnemius, an ankle extensor, is normally inhibited in response to a tail-up tilt, reducing the downhill torque (rotational force) and reducing body tilt relative to gravity. With vestibular loss the muscle is activated, which increases the downhill torque and increases body tilt, causing loss of balance. Platform displacement begins at time zero. 2. The directional tuning of a left hip extensor muscle to platform tilt switches to the opposite quadrant after vestibular loss.

B Linear motion

1 Postural response is appropriate, but exaggerated

2 Directional tuning of muscle is normal

B. Immediately after vestibular loss the postural response to horizontal motion of the platform is appropriate but exceeds that of control trials. 1. The response of the gluteus medius, a hip extensor and abductor, has normal latency but larger amplitude. In the control condition the center of mass (CoM) moves away from the origin and returns in a smooth trajectory. After vestibular loss the CoM displacement follows a trajectory similar to that of the control trace, but because of the larger muscle activation it peaks earlier in time. In the return phase the center of mass overshoots the origin and oscillates. Platform movement begins at time zero. (A, anterior; P, posterior.) 2. The directional tuning of a left hip extensor muscle is the same with and without vestibular function when activated by linear motion of the platform. The amplitude of activation of the muscle is somewhat larger when vestibular function is lost.

motion of the support surface has the appropriate directional tuning and latency, even in the acute stage prior to vestibular compensation.

Why does the absence of vestibular signals cause difficulty with tilt but not with linear motion? The answer lies in how the nervous system determines the direction of vertical. Gravity is the main force that causes the body to fall. As the support surface tilts, healthy subjects orient to gravity using vestibular information to remain upright. In contrast, subjects without vestibular function use somatosensory inputs to orient themselves to the support surface and consequently fall downhill as the surface tilts. During linear motion, however, gravitational and surface vertical are collinear, and somatosensory signals are sufficient to compute the correct postural response. Although visual inputs also provide a vertical reference, visual processing is too slow to participate in the automatic postural response to rapid tilt, especially soon after the loss of vestibular function.

Without vestibular information the response to linear motion of the support surface is larger than normal (hypermetria), leading to overbalancing and instability (Figure 41–10B). Hypermetria is a major cause of ataxia when vestibular information is lost. Vestibular hypermetria may result from reduced cerebellar inhibition of the motor system, for the loss of vestibular inputs reduces the drive to the inhibitory Purkinje cells.

Humans and cats are quite ataxic immediately after loss of the vestibular apparatus. The head and trunk show marked instability, stance and gait are broadbased, and walking follows a weaving path with frequent falling. Instability is especially great on turning the head, probably because trunk motion cannot be distinguished from head motion using somatosensory information alone. Paul Stapley and colleagues showed that cats lacking vestibular inputs actively push themselves toward the side of a voluntary head turn, likely because somatosensory inputs that encode trunk and head motion are misinterpreted in the absence of vestibular inputs. The postural system erroneously senses that the body is falling to the side away from the head turn and generates a response in the opposite direction, resulting in imbalance.

Immediately following vestibular loss, neck muscles are abnormally activated during ordinary movements and often the head and trunk are moved together as a unit. After several months routine movement becomes more normal through vestibular compensation, which may involve greater reliance on the remaining sensory information. However, more challenging tasks are hampered by a residual hypermetria, stiffness in head-trunk control, and instability, especially when

visual and somatosensory information is unavailable for postural orientation. Vestibular information is critical for balance when visual information is reduced and the support surface is not stable, for example at night, on a sandy beach, or on a boat's deck.

Visual Information Provides Advance Knowledge of Potentially Destabilizing Situations and Assists in Orienting to the Environment

Visual inputs provide the postural system with orientation and motion information from both near and far. Vision reduces body sway when standing still and provides stabilizing cues, especially when a new balancing task is attempted or balance is precarious. Skaters and dancers maintain stability while spinning by fixing their gaze on a point in the visual field. However, visual processing is too slow to significantly affect the postural response to a sudden disturbance of balance. Vision does play an important role in anticipatory postural adjustments during voluntary movements, such as planning where to place the feet when walking over obstacles.

Vision can have a powerful influence on postural orientation, as anyone can attest who has seen a movie filmed from the perspective of a moving viewer and projected on a large screen. Simulated rides in a roller coaster or plane, for example, can induce strong sensations of motion along with activation of postural muscles. An illusion of movement is induced when sufficiently large regions of the visual field are stimulated, as when a large disk in front of a standing subject is rotated. The subject responds to this illusion by tilting his body; clockwise rotation of the visual field is interpreted by the postural system as the body falling to the left, to which the subject compensates by leaning to the right (Figure 41–9B). The rate and direction of optic flow—the flow of images across the retina as people move about—provide clues about body orientation and movement.

Information from a Single Sensory Modality Can Be Ambiguous

Any one sensory modality alone may provide ambiguous information about postural orientation and body motion. The visual system, for example, cannot distinguish self-motion from object motion. We have all experienced the fleeting sensation while sitting in a stationary vehicle of not knowing whether we are moving or the adjacent vehicle is moving.

Vestibular information can also be ambiguous for two reasons. First, vestibular receptors are located in the head and therefore provide information about acceleration of the head but not about the rest of the body. The postural control system cannot use vestibular information alone to distinguish between the head tilting on a stationary trunk and the whole body tilting by rotation at the ankles, both of which activate the semicircular canals and otolith organs. Additional information from somatosensory receptors is required to resolve this ambiguity. The otolith organs also cannot distinguish between acceleration owing to gravity and linear acceleration of the head. Tilting to the left, for example, can produce the same otolithic stimulation as acceleration of the body to the right (Figure 41–11).

Studies of vestibulo-ocular reflexes suggest there are neural circuits that can disambiguate the head-tilt

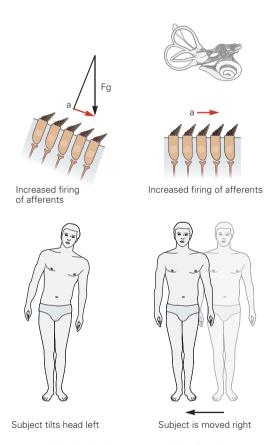

Figure 41–11 Vestibular inputs regarding body posture and motion can be ambiguous. The postural system cannot distinguish between tilt and linear acceleration of the body based on otolithic inputs alone. The mechanoreceptors of the vestibular system are hair bundles that bend in response to shearing forces, thus changing the firing rate of the tonically active sensory afferents. The same shearing force can result from tilting of the head (left), which exposes the hair cells to a portion of the acceleration (a) owing to gravity (Fg), or from horizontal linear acceleration of the body (right).

component of a linear acceleration by using a combination of canal and otolith inputs. Output from this circuit may allow the postural system to determine the orientation of gravity relative to the head regardless of head position and motion. The distinction between tilt and linear motion is especially important while standing on an unstable or a tilting surface.

Somatosensory inputs may also provide ambiguous information about body orientation and motion. When we stand upright mechanoreceptors in the soles of our feet and proprioceptors in muscles and joints signal the motion of our body relative to the support surface. But somatosensory inputs alone cannot distinguish between body and surface motion, for example whether ankle flexion stems from forward body sway or tilting of the surface. Our common experience is that the ground beneath us is stable and that somatosensory inputs reflect movements of the body's center of mass as we sway. But surfaces may move relative to the earth, such as a boat's deck, or may be pliant under our weight, like a soft or spongy surface. Therefore, somatosensory information must be integrated with vestibular and visual inputs to give the nervous system an accurate picture of the stability and inclination of the support surface and of our body's relationship to earth vertical.

The Postural Control System Uses a Body Schema that Incorporates Internal Models for Balance

Because of the mechanical complexity of the body, with its many skeletal segments and muscles, the nervous system requires a coherent representation of the body and its interaction with the environment. To execute the simple movement of raising your hand and touching your nose with your index finger while your eyes are closed, your nervous system must know the characteristics (length, mass, and connections) of each segment of the arm, the shoulder, and head as well as the orientation of your arm with respect to the gravity vector and your nose. Thus information from multiple sensory systems is integrated into a central representation of the body and its environment, often called the body schema.

The body schema for postural control, as developed by Viktor Gurfinkel, is not simply a sensory map like the somatotopic representation of the skin in primary sensory cortex. Instead, it incorporates internal models of the body's relationship with the environment (see Chapter 33). This representation is used to compute appropriate anticipatory and automatic postural reactions to maintain balance and postural orientation.

A simplified example of such an internal model is one in which the body is represented as a single segment

hinged at the foot (Figure 41–12A). The internal model generates an estimate of the orientation of the foot in space, which also serves as an estimate of the orientation of the support surface, a variable that cannot be directly sensed.

Henry Head, a neurologist working in the early part of the 20th century, described the body schema as a dynamic system in which both spatial and temporal features are continually updated, a concept that remains current. To allow adequate planning of movement strategies, the body schema must incorporate not only the relationship of body segments to space and to each other but also the mass and inertia of each segment and an estimate of the external forces acting on the body including gravity.

Another component of the body schema is a model of the sensory information expected as a result of a movement. Disorientation or motion sickness may result when the actual sensory information received by the nervous system does not match the expected sensory information, as in the microgravity environment of space flight. With continued exposure to the new environment, however, the model is gradually updated until expected and actual sensory information agree and the person is no longer spatially disoriented.

The internal model for balance control must be continually updated, both in the short term, as we use experience to improve our balance strategies, and in the long term, as we age and our bodies change in shape and size. One way the body schema is updated is by changing the weighting of each of the sensory modalities.

The Influence of Each Sensory Modality on Balance and Orientation Changes According to Task Requirements

The postural control system must be able to change the relative sensitivity or weighting of different sensory modalities to accommodate changes in the environment and movement goals. Subjects on a firm, stable surface tend to rely primarily on somatosensory information for postural orientation. When the support surface is unstable subjects depend more on vestibular and visual information. However, even when the support surface is not stable, light touch with a fingertip on a stable object is more effective than vision in maintaining postural orientation and balance. Vestibular information is particularly critical when visual and somatosensory information is ambiguous or absent, such as when skiing downhill or walking below deck on a ship.

The weighting of each sensory system changes with the type of task and with the characteristics of

the environment. This change can be demonstrated in an experiment in which subjects are blindfolded and asked to stand quietly on a surface that is slowly tilted by varying amounts, up to 8 degrees in magnitude. For tilts of less than 2 degrees all subjects sway with the platform, suggesting that they use somatosensory information to orient their body to the support surface. At larger tilts healthy subjects attenuate their sway and orient their posture more with respect to gravitational vertical than to the surface, as if relying more on vestibular information. In contrast, patients who have lost vestibular function persist in swaying along with the platform and subsequently fall (Figure 41–12B). This behavior accords with the patients' inappropriate automatic postural response to rapid platform tilts.

Studies such as these suggest that when people are standing on moving or unstable surfaces, the weighting of vestibular and visual information increases whereas that of somatosensory information decreases. Any sensory modality may dominate at a particular time, depending on the conditions of postural support and the specific motor behavior to be performed.

Control of Posture Is Distributed in the Nervous System

Postural orientation and balance are achieved through the dynamic and context-dependent interplay among all levels of the central nervous system, from the spinal cord to cerebral cortex.

Spinal Cord Circuits Are Sufficient for Maintaining Antigravity Support but Not Balance

Adult cats with complete spinal transection at the thoracic level can be trained to support the weight of their hindquarters with fairly normal hind limb and trunk postural orientation, but they have little control of balance. These animals do not exhibit normal postural responses in their hind limbs when the support surface moves. Their response to horizontal motion consists of small, random, and highly variable bursts of activity in extensor muscles that are considerably delayed compared to normal activity, whereas postural activity in flexor muscles is absent (Figure 41–13). Active balance is absent despite the fact that extensors and flexors can be recruited for other movements such as stepping on a treadmill.

An adult cat with a spinal transection can stand independently for only short periods of time and within a narrow range of stability; head turns in particular cause the animal to lose balance. What stability

A Internal model for estimating physical reality

Figure 41–12 Many types of sensory signals are integrated and weighted in an internal model that optimizes balance and orientation. (Adapted, with permission, from Peterka 2002.)

A. The simple example of a person standing on a tilted surface illustrates how the nervous system might estimate physical variables that are not sensed directly. The physical variables are body tilt with respect to earth vertical or space (BS), and body angle relative to the foot (BF). The angle of the foot in space (FS) is simply the difference BS – BF. The neural estimate of body in space (bs) comes from vestibular and other receptors that detect tilt of the body relative to gravity. The neural estimate of body angle to foot (bf) comes from somatosensory signals related to ankle joint angle. The internal model for estimating physical reality, bs – bf, produces a neural estimate of the foot in space (fs). Such estimates of the physical world are continually updated based on experience.

B. Sensory information is weighted dynamically to maintain balance and orientation under varying conditions. The figure illustrates findings from an experiment in which human subjects stood blindfolded on a platform that slowly rotated continuously in the toes-up or toes-down direction at amplitudes of up to

8 degrees (peak to peak). 1. Body-sway angle is measured relative to gravitational vertical during platform tilt and expressed as root mean square (RMS) sway in degrees. The dashed line represents equal platform and body sway; for example, for a platform tilt of 4 degrees an equal amount of body sway is 1 degree RMS. In control subjects the body and platform sway are equal for small platform tilts up to 2 degrees, suggesting that people normally use somatosensory signals to remain perpendicular to the platform (minimizing changes in ankle angle). With larger platform tilts, body sway does not increase much beyond 0.5 degree RMS. In contrast, subjects with vestibular loss sway even more than the platform (1.5 degrees RMS of body tilt at 4 degrees of platform tilt) and cannot remain standing at platform tilts above 4 degrees. Thus, when both vestibular and visual signals are absent, a person orients only to the support surface and has difficulty maintaining balance. 2. In control subjects the influence of somatosensory input decreases with increasing platform tilt while the influence of vestibular input increases. At larger tilt angles the greater influence of vestibular input minimizes the degree of body sway away from gravitational vertical.

Platform tilt (deg)

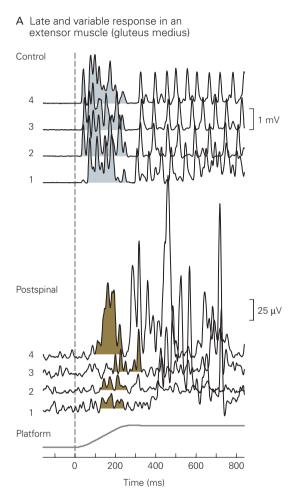

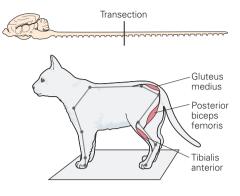

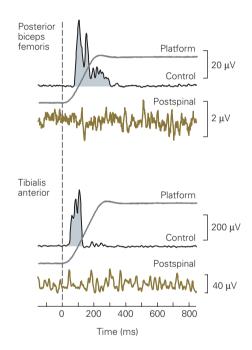

Figure 41–13 Spinal circuits alone do not generate automatic postural responses for balance. In this experiment automatic postural responses to horizontal motion are recorded before and after complete transection of the spinal cord at the level of the sixth thoracic vertebra. This transection leaves the lumbar spinal cord intact but isolated from higher neural centers. (Adapted, with permission, from Macpherson and Fung 1999.)

A. Electromyogram (EMG) records from a left hind limb extensor are disorganized after spinal transection. In four trials after

B No evoked activity in flexor muscles

transection the response amplitude of the left gluteus medius is greatly reduced following forward and rightward motion of the platform. In addition, the amplitude and onset time vary greatly between trials. Note that the scale of the postspinal records is considerably smaller than that of the control records.

B. Flexor muscles in the left hind limb are normally activated by platform motion in the backward and leftward direction. After spinal transection the flexors do not respond to translation. The posterior biceps femoris is a knee flexor; tibialis anterior is an ankle dorsiflexor.

there is likely results from the broad base of support afforded by quadrupedal stance, the stiffness of the tonically contracting hind limb extensors that support the weight of the hindquarters, and active compensation by forelimbs that continue to produce postural responses. Humans with spinal cord injuries have various amounts of antigravity muscle tonus but lack automatic postural responses below the level of the lesion. These results emphasize that antigravity support and balance control are distinct mechanisms and that the control of balance requires the involvement of supraspinal circuits.

The Brain Stem and Cerebellum Integrate Sensory Signals for Posture

If spinal circuits alone are not capable of producing automatic postural responses, what supraspinal centers are responsible for these responses? Although the answer to this question remains unknown, good candidates include the brain stem and cerebellum, which are highly interconnected and work together to modulate the descending commands to spinal motor centers of the limbs and trunk. These regions have the inputoutput structure that would be expected of centers for postural control.

Muscle synergies for automatic postural responses may be organized in the brain stem, perhaps the reticular formation. However, adaptation of postural synergies to changes in the environment and task demands may require cerebellar influence.

Two regions of the cerebellum influence orientation and balance: the vestibulocerebellum (nodulus, uvula, and fastigial nucleus) and the spinocerebellum (anterior lobe and interpositus nucleus). These regions are interconnected with the vestibular nuclei and reticular formation of the pons and medulla (see Figure 42-3). Lesions of the brain stem and vestibulocerebellum produce a variety of deficits in head and trunk control and a tendency to tilt from vertical, even with eyes open, suggesting a deficit in the internal representation of postural orientation. Lesions of the spinocerebellum result in excessive postural sway that is worse with the eyes closed, ataxia during walking, and hypermetric postural responses, suggesting deficits in balance reactions. Certain regions in the pons and medulla facilitate or depress extensor tonus and could thereby influence antigravity support.

The brain stem and cerebellum are sites of integration of sensory inputs, perhaps generating the internal model of body orientation and balance. Vestibular and visual inputs are distributed to brain stem centers (see Chapter 45) and the vestibulocerebellum. The spinocerebellum receives signals from rapidly conducting proprioceptive and cutaneous fibers. More slowly conducting somatosensory fibers project to the vestibular nuclei and reticular formation.

Two major descending systems carry signals from the brain stem and cerebellum to the spinal cord and could therefore trigger the automatic postural response for balance and orientation. The medial and lateral vestibulospinal tracts originate from the vestibular nuclei, and the medial and lateral reticulospinal tracts originate from the reticular formation of the pons and medulla (see Figure 42–7). Lesions of these tracts result in profound ataxia and postural instability. In contrast,

lesions of the corticospinal and rubrospinal tracts have minimal effect on balance even though they produce profound disturbance of voluntary limb movements.

The Spinocerebellum and Basal Ganglia Are Important in Adaptation of Posture

Patients with spinocerebellar disorders, such as alcoholic anterior-lobe syndrome, and basal-ganglion deficits, such as Parkinson disease, experience postural difficulties. This suggests that the spinocerebellum and basal ganglia play complementary roles in adapting postural responses to changing conditions.

The spinocerebellum is where the magnitude of postural responses is adapted based on experience. The basal ganglia are important for quickly adjusting the postural set when conditions suddenly change, to ensure that postural responses are approximately correct. Both the spinocerebellum and the basal ganglia regulate muscle tone and force for voluntary postural adjustments. They are not necessary, however, for triggering or constructing the basic postural patterns.

Patients with disorders of the spinocerebellum have difficulty adjusting the magnitude of balance adjustments over the course of repeated trials but can readily adapt postural responses immediately after a change in conditions. For example, a patient standing on a movable platform exhibits appropriate postural responses when platform velocity is increased with each trial. These postural adjustments rely on velocity information, which is encoded by somatosensory inputs at the beginning of platform movement.

In contrast, when the amplitude of platform movement can be predicted on the basis of repeated presentation, a patient is unable to adjust the amplitude of his response to that of the anticipated perturbation. Because the amplitude of platform movement is not known until the platform has stopped moving, well after the initial postural response is complete, a subject must use his experience from one trial to modify his response in a subsequent trial of the same amplitude. Whereas a healthy subject does this quite readily, a patient with spinocerebellar disorders is unable to efficiently adapt his postural responses based on recent experience (Figure 41–14A).

In a healthy subject muscle activity during sudden backward motion of the support surface is appropriately scaled to counteract the forward sway induced by the perturbation. A subject with spinocerebellar disease always over-responds, although the timing of muscle activation is normal (Figure 41–14B). As a result, this individual returns beyond the upright

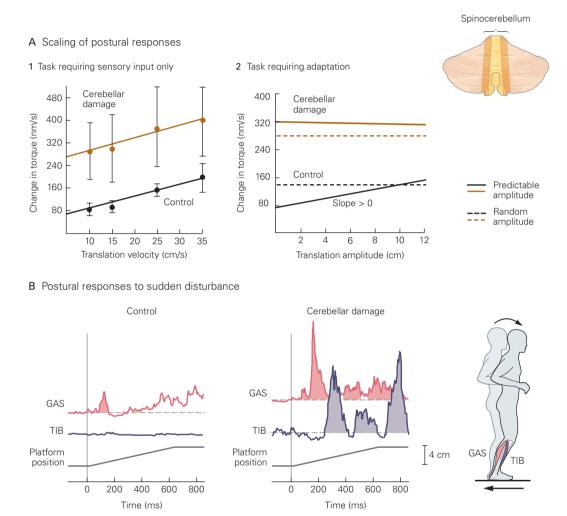

Figure 41–14 The spinocerebellum has a role in adapting postural responses to changing conditions. The spinocerebellum is important for adapting postural responses based on experience. Patients with a spinocerebellar disorder can use immediate sensory input but not experience to adjust automatic postural responses. (Adapted, with permission, from Horak and Diener 1994.)

A. 1. A subject stands on a platform that is moved horizontally; the velocity is increased on each trial. Maintaining balance requires scaling responses to the velocity of the platform using sensory feedback. The adjustments in a subject with a spinocerebellar disorder have the same regression coefficient (slope) as those of a control subject, even though in each trial the responses are larger and more variable than those of the control subject. 2. When subjects are required to anticipate and adapt to platform translation, the postural adjustments in the spinocerebellar subject are compromised. When translation

amplitude is random, responses are large, as if the subject expected a large translation. When trials with the same amplitude are repeated, a control subject learns to predict the amplitude of the disturbance and adjust his response. In contrast, a spinocerebellar subject shows no improvement in performance; he cannot use his experience in one trial to adjust his responses in subsequent trials. The responses are large, as if the subject always expected the large translation.

B. Postural responses to sudden disturbances are hypermetric in spinocerebellar patients. In this experiment subjects stand on a platform that is moved backward (6 cm amplitude at 10 cm/s). In a control subject the onset of movement evokes a small burst of activity in the gastrocnemius (GAS), an ankle extensor. In a subject with damage to the anterior lobe of the cerebellum the muscle responses are overly large, with bursts of activity alternating between the gastrocnemius and its antagonist, the tibialis anterior (TIB).

position and oscillates back and forth. Reminiscent of the hypermetria observed immediately after labyrinthectomy, cerebellar hypermetria may also result from loss of Purkinje-cell inhibition on spinal motor centers

A patient with Parkinson disease can, with sufficient practice, gradually modify his postural responses but has difficulty changing responses when conditions change suddenly. Such postural inflexibility is seen when initial posture changes. For example, when a normal subject on a movable platform switches from standing upright to sitting on a stool, the pattern of his automatic postural response to backward movement of the platform changes immediately. Because legmuscle activity is no longer necessary after the switch from standing to sitting, this component ceases to be recruited.

In contrast, a patient with Parkinson disease employs the same muscle activation pattern for both sitting and standing (Figure 41–15). L-DOPA replacement therapy does not improve the patient's ability to switch postural set. With repetition of trials in the seated posture, however, the leg-muscle activity eventually disappears, showing that enough experience permits adaptation of postural responses. A patient with Parkinson disease also has difficulty when instructed to increase or decrease the magnitude of a postural response, a difficulty that is consistent with the inability to change cognitive sets quickly.

A patient with a basal ganglion disorder has problems with postural tone and force generation in addition to an inability to adapt to changing conditions. The bradykinesia (slowness of movement) of Parkinson disease is reflected in slow development of force in postural responses and the disease's rigidity is manifested in co-contraction and stiffness. L-DOPA replacement greatly improves a patient's ability to generate not only forceful voluntary movements but also the accompanying postural adjustments, such as rising onto the toes and gait. However, neither the automatic postural response to an unexpected disturbance nor postural adaptation is improved by L-DOPA, suggesting that these functions involve the nondopaminergic pathways affected by Parkinson disease.

Cerebral Cortex Centers Contribute to Postural Control

Centers in the cerebral cortex influence postural orientation and equilibrium, including both anticipatory and automatic postural responses. Most voluntary movements, which are initiated in the cerebral cortex, require postural adjustments that must be integrated with the

primary goal of the movement in both timing and amplitude. Where this integration occurs is not clear.

The cerebral cortex has more control over anticipatory postural adjustments than automatic postural reactions. However, recent electroencephalographic (EEG) studies show that areas of cerebral cortex are activated by anticipation of a postural disturbance before an automatic postural response is initiated. This finding is consistent with the idea that the cortex optimizes balance control as part of motor planning.

The supplementary motor area and temporoparietal cortex have both been implicated in postural control. The supplementary motor area (see Chapter 38) is likely involved with anticipatory postural adjustments that accompany voluntary movements. The temporoparietal cortex appears to integrate sensory information and may contain internal models for perception of body verticality. Lesions of insular cortex can impair perception of the visual vertical whereas lesions of superior parietal cortex impair perception of postural vertical, and either of these defects may impair balance when standing on an unstable support.

Sensorimotor cortex receives somatosensory inputs signaling balance disturbances and postural responses. However, this region is not essential for automatic postural adjustments. Jean Massion and colleagues have shown that lesioning the motor cortex in cats impairs the lifting of the forelimb evoked by light touch during stance, but does not abolish the accompanying postural adjustment in the contralateral forelimb. Although the sensorimotor cortex is not responsible for postural adjustments, it may have a role in the process.

Behavioral studies, too, have implicated cortical processes in postural control. Control of posture, like control of voluntary movement, requires attention. When subjects must press a button following a visual or auditory cue while also maintaining balance, their reaction time increases with the difficulty of the task (balancing on one foot versus sitting, for example). Moreover, when subjects try to perform a cognitive task while actively maintaining posture, the performance of either or both can degrade. For example, when a subject is asked to count backward by threes while standing on one foot, both the cognitive task and postural adjustment deteriorate. The timing of automatic postural responses to unexpected disturbances is little affected by cognitive interference.

Balance control is also influenced by emotional state, thus implicating the limbic system in posture control. Fear of falling, for example, can increase postural tone and stiffness, reduce sway area, increase sway velocity, and alter balancing strategies in response to disturbances.

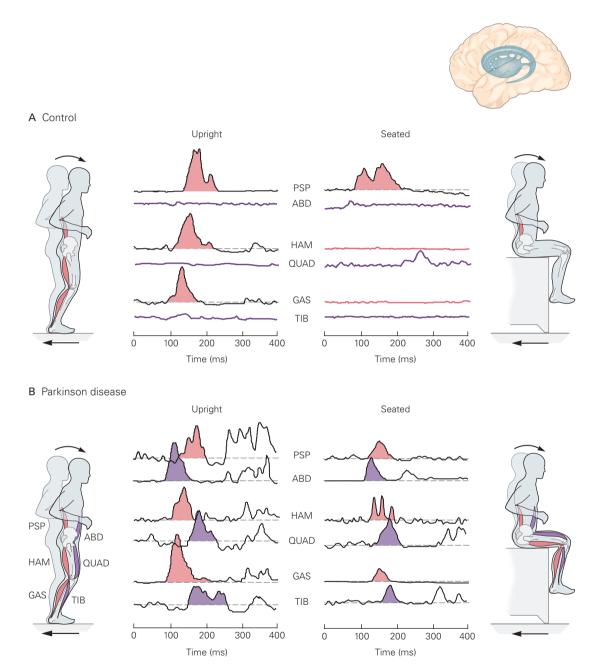

Figure 41–15 The basal ganglia are important for adapting postural responses to a sudden change in initial conditions. (Adapted, with permission, from Horak, Nutt, and Nashner 1992.)

A. When a normal subject switches from upright stance to sitting he immediately modifies his response to backward movement of the support platform. The postural response to movement while seated does not involve the leg muscles—the gastrocnemius (GAS) and hamstrings (HAM)—but does

activate the paraspinal muscles (PSP) and with shorter latency than in the response to movement while standing. (ABD, abdominals; QUAD, quadriceps; TIB, tibialis anterior.)

B. A patient with Parkinson disease does not suppress the legmuscle response in the first trial after switching from standing to sitting. The postural response of this subject is similar for both initial positions: antagonist muscles (**purple**) are activated along with agonists (**pink**).

Although the roles of specific areas of cerebral cortex in postural control are largely undefined, there is no doubt that the cortex is important for learning new, complex postural strategies. The cortex must be involved in the amazing improvement in balance and postural orientation of athletes and dancers who use cognitive information and advice from coaches. In fact, the cerebral cortex is involved in postural control each time we consciously maintain our balance while walking across a slippery floor, standing on a moving bus, or waiting tables on a rocking ship.

An Overall View

Although we are usually unaware of it, the posture control system is active during most of the activities we perform daily. Automatic postural adjustments prevent falling when some external force disrupts our balance. These responses are not simple reflexes but are highly organized, flexible, and adaptive patterns of muscle activation. Anticipatory postural adjustments accompany our voluntary movements to maintain balance and orientation.

Somatosensory, vestibular, and visual inputs all contribute to postural control for balance and orientation with differing degrees of influence as our environment changes. Many areas of the nervous system integrate sensory inputs to form a unified representation of the body's orientation and motion and of the environment. This body schema is used to compute the appropriate postural adjustments to maintain balance.

The postural system is highly adaptive, both in the short term to optimize postural behavior to a continually changing environment, and in the long term to accommodate changes in body morphology and mechanics caused by growth and development, aging, disease, and injury.

An Overall View

The Cerebellum constitutes only 10% of the total volume of the brain but contains more than one-half of its neurons. The structure comprises a series of highly regular, repeating units, each of which contains the same basic microcircuit. Different regions of the cerebellum receive projections from different parts of the brain and spinal cord and project to different motor systems. Nonetheless, the similarity of the architecture and physiology in all regions of the cerebellum implies that different regions of the cerebellum perform similar computational operations on different inputs.

The symptoms of cerebellar damage in humans and experimental animals give the clear impression that the cerebellum participates in the control of movement. Thus we describe these symptoms because knowledge of them, in addition to being critical for the clinician, constrains conjecture about the exact role of the cerebellum in controlling behavior. The goal of cerebellar research is to understand how the connections and physiology of cerebellar neurons define the function of the cerebellum. Thus a major part of this chapter covers the fundamentals of cerebellar physiology and anatomy.

Finally, there is a relationship between cerebellar operation and more theoretical concepts of "internal models" in motor control (see Chapter 33). A fundamental

precept of modern cerebellar research is that these internal representations of the external world are implemented in the cerebellum. The cerebellum could adjust motor performance by using its learning capabilities to alter the internal models to match any changes in the motor effectors of the external world. Thus at the conclusion of this chapter we discuss cerebellar learning and its possible relationship to internal models.

Cerebellar Diseases Have Distinctive Symptoms and Signs

Disorders of the human cerebellum result in disruptions of normal movement, described originally by Joseph Babinski in 1899 and by Gordon Holmes in the 1920s. These disruptions are in stark contrast to the paralysis caused by damage to the cerebral cortex. We cannot yet link normal cerebellar structure and function to the symptoms of cerebellar damage in humans, but the fact that movements are disrupted rather than abolished and the nature of the disruptions are important clues about cerebellar function.

Cerebellar disorders are manifested in four symptoms. The first is *hypotonia*, a diminished resistance to

passive limb displacements. Hypotonia is also thought to be related to so-called "pendular reflexes." The leg normally comes to rest immediately after a knee jerk produced by a tap on the patellar tendon with a reflex hammer. In patients who have cerebellar disease, however, the leg may oscillate like a pendulum as many as eight times before coming to rest.

The second symptom is *astasia-abasia*, an inability to stand or walk. Astasia is loss of the ability to maintain a steady limb or body posture across multiple joints. Abasia is loss of the ability to maintain upright stance against gravity. When sitting or standing, many cerebellar patients compensate by spreading their feet, an attempt to stabilize balance by increasing the base of support (see Chapter 41). They move their legs irregularly and often fall.

The third symptom is *ataxia*, the abnormal execution of multi-jointed voluntary movements, characterized by lack of coordination. Patients have problems initiating responses with the affected limb and controlling the size of a movement (dysmetria) and the rate and regularity of repeated movements (Figure 42–1). This last deficit, first described by Babinski, is most readily demonstrated when a patient attempts to perform rapid alternating movements, such as alternately touching

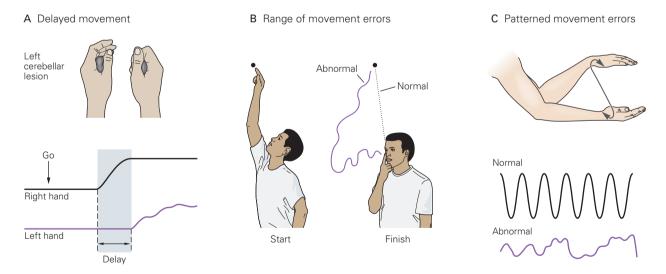

Figure 42-1 Typical defects observed in cerebellar diseases.

A. A lesion in the left cerebellar hemisphere delays the initiation of movement. The patient is told to clench both hands at the same time on a "go" signal. The left hand is clenched later than the right, as is evident in the recordings from a pressure bulb transducer squeezed by the patient.

B. A patient moving his arm from a raised position to touch the tip of his nose exhibits inaccuracy in range and direction (dysmetria) and moves his shoulder and elbow separately (decomposition of movement). Tremor increases as the finger approaches the nose.

C. A subject was asked to alternately pronate and supinate the forearm while flexing and extending at the elbow as rapidly as possible. Position traces of the hand and forearm show the normal pattern of alternating movements and the irregular pattern (dysdiadochokinesia) typical of cerebellar disorder.

the back and the palm of one hand with the palm of the other. Patients cannot sustain a regular rhythm or produce an even amount of force, a sign referred to as *dysdiadochokinesia* (Greek, impaired alternating movement). Holmes also noted that patients made errors in the timing of the components of complex multi-joint movements (decomposition of movement) and frequently failed to brace proximal joints against the forces generated by the movement of more distal joints.

The fourth symptom of cerebellar disease is a form of tremor at the end of a movement, when the patient attempts to stop the movement by using antagonist muscles. This *action* (or *intention*) *tremor* is the result of a series of erroneous corrections of the movement. Once a movement is clearly headed in the wrong direction, attempts to make corrections fail repeatedly and the hand oscillates irregularly around the target in a characteristic *terminal tremor*. This behavior clearly suggests that the cerebellum normally is responsible for the properly timed sequence of activation in agonist and antagonist muscles and that loss of proper timing causes movements that, although initiated in the correct direction, cannot be controlled or brought to an accurate endpoint.

One conspicuous feature of cerebellar disorders is a loss of the automatic, unconscious nature of most movements, especially for motor acts made up of multiple sequential movements. One of Holmes's patients, who had a lesion of his right cerebellar hemisphere, reported that "movements of my left arm are done subconsciously, but I have to think out each movement of the right arm. I come to a dead stop in turning and have to think before I start again." Normally movement is controlled seamlessly by cerebellar inputs and outputs; with a malfunctioning cerebellum it seems that the cerebral cortex needs to play a more active role in programming the details of motor actions.

The Cerebellum Has Several Functionally Distinct Regions

The cerebellum occupies most of the posterior cranial fossa. It is composed of an outer mantle of gray matter (the cerebellar cortex), internal white matter, and three pairs of deep nuclei: the fastigial nucleus, the interposed nucleus (itself comprising the emboliform and globose nuclei), and the dentate nucleus (Figure 42–2A).

The cerebellum is connected to the dorsal aspect of the brain stem by three symmetrical pairs of peduncles: the *inferior cerebellar peduncle* (also called the restiform body), the *middle cerebellar peduncle* (or brachium pontis), and the *superior cerebellar peduncle* (or brachium conjunctivum). Most of the output axons of

the cerebellum arise from the deep nuclei and project through the superior cerebellar peduncle. The main exception is a group of Purkinje cells in the flocculonodular lobe that projects to vestibular nuclei in the brain stem.

The surface of the cerebellum is highly convoluted, with many parallel folds called *folia* (Latin, leaves). Two deep transverse fissures divide the cerebellum into three lobes. The primary fissure on the dorsal surface separates the anterior and posterior lobes, which together form the body of the cerebellum (Figure 42–2A). The posterolateral fissure on the ventral surface separates the body of the cerebellum from the smaller flocculo-nodular lobe (Figure 42–2B). Each lobe extends across the cerebellum from the midline to the most lateral tip.

In the orthogonal, anterior-posterior direction two longitudinal furrows divide three regions: the midline *vermis* (Latin, worm) and the *cerebellar hemispheres*, each of which is split into intermediate and lateral regions (Figure 42–2A).

The cerebellum is also divisible into three areas that have distinctive roles in different kinds of movements: the vestibulocerebellum, spinocerebellum, and cerebrocerebellum (Figure 42–3). The *vestibulocerebellum* consists of the flocculonodular lobe and is the most primitive part of the cerebellum, appearing first in fishes. It receives vestibular and visual inputs, projects to the vestibular nuclei in the brain stem, and participates in balance, other vestibular reflexes, and eye movements.

The spinocerebellum comprises the vermis and intermediate parts of the hemispheres and appears later in phylogeny. It is so named because it receives somatosensory and proprioceptive inputs from the spinal cord. The vermis receives visual, auditory, and vestibular input as well as somatic sensory input from the head and proximal parts of the body. It projects by way of the fastigial nucleus to cortical and brain stem regions that give rise to the medial descending systems controlling proximal muscles of the body and limbs. The vermis governs posture and locomotion as well as eye movements. The adjacent intermediate parts of the hemispheres also receive somatosensory input from the limbs. Neurons here project to the interposed nucleus, which provides inputs to lateral corticospinal and rubrospinal systems and controls the more distal muscles of the limbs and digits.

The *cerebrocerebellum* comprises the lateral parts of the hemispheres. These areas are phylogenetically most recent and are much larger in humans and apes than in monkeys and cats. Almost all of the inputs to and outputs from this region involve connections with the cerebral cortex. The output is transmitted through the *dentate nucleus*, which projects to motor, premotor, and prefrontal cortices. The lateral hemispheres have

many functions but seem to participate most extensively in planning and executing movement. They may also have a role in certain cognitive functions unconnected with motor planning, such as working memory. There is now some correlative evidence implicating the cerebellar hemispheres in aspects of schizophrenia (see Chapter 62) and autism (see Chapter 64).

The Cerebellar Microcircuit Has a Distinct and Regular Organization

The cellular organization of the cerebellar microcircuit is striking, and one of the premises of cerebellar

research has been that the details of the microcircuit are an important clue to how the cerebellum works. Four major features of the microcircuit are described in the next four subsections.

Neurons in the Cerebellar Cortex Are Organized into Three Layers

The three layers of the cerebellar cortex possess distinct kinds of neurons and perform different operations (Figure 42–4).

The deepest or *granular layer* is the input layer. It contains a vast number of granule cells, estimated at 100 billion, which appear in histological sections

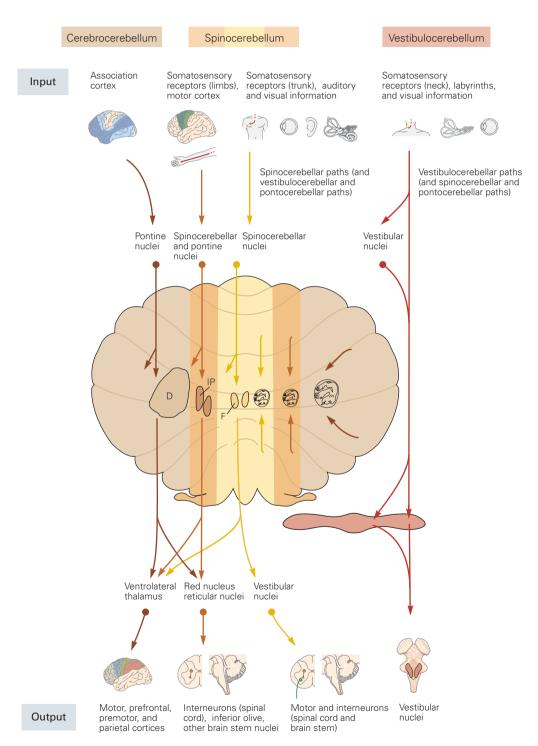

Figure 42–3 The three functional regions of the cerebellum have different inputs and different output targets. In the figure the cerebellum is unfolded, and arrows show the inputs and outputs of the different functional areas. The body maps in

the deep nuclei are based on anatomical tracing and single-cell recordings in nonhuman primates. (D, dentate nucleus; IP, interposed nucleus; F, fastigial nucleus.) (Adapted, with permission, from Thach 1980.)

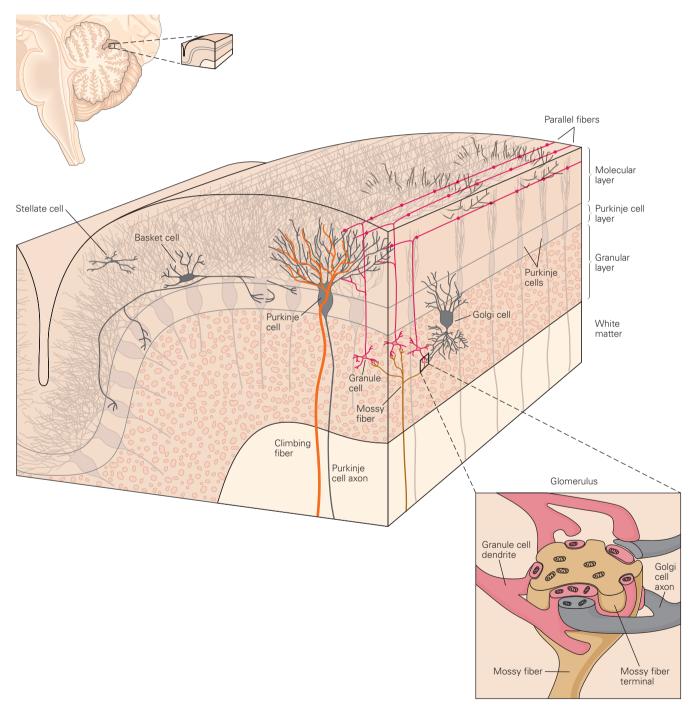

Figure 42–4 The cerebellar cortex contains five types of neurons organized into three layers. A vertical section of a single cerebellar folium illustrates the general organization of the cerebellar cortex. The detail of a cerebellar glomerulus in the granular layer is also shown. A glomerulus is the synaptic

complex formed by the bulbous axon terminal of a mossy fiber and the dendrites of several Golgi and granule cells. Mitochondria are present in all of the structures in the glomerulus, consistent with their high metabolic activity. as small, densely packed, darkly stained nuclei. This layer also contains a few larger Golgi interneurons and, in some cerebellar regions, a smattering of other neurons such as cells of Lugaro, unipolar brush cells, and chandelier cells. The mossy fibers, one of the two principal afferent inputs to the cerebellum, terminate in this layer. The bulbous terminals of the mossy fibers excite granule cells and Golgi neurons in synaptic complexes called *cerebellar glomeruli* (Figure 42–4). As we will see later when discussing recurrent circuits in the cerebellum, Golgi cells inhibit granule cells.

The middle, or *Purkinje cell layer*, is the output layer of the cerebellar cortex. This layer consists of a single sheet of Purkinje cells bodies, which are 50 to 80 μ m in diameter. The fan-like dendrites of Purkinje cells extend upward into the molecular layer where they receive inputs from the second major type of afferent fiber in the cerebellum, the climbing fibers, as well as from inhibitory and excitatory interneurons. Purkinje cell axons conduct the entire output of the cerebellar cortex, projecting to the deep nuclei in the underlying white matter or to the vestibular nuclei in the brain stem where the GABA (γ -aminobutyric acid) released by their terminals has an inhibitory action.

The outermost, or *molecular layer*, is an important processing layer of the cerebellar cortex. It contains the cell bodies and dendrites of two types of inhibitory interneurons, the stellate and basket cells, as well as the extensive dendrites of Purkinje cells. It also contains the axons of the granule cells, called the parallel fibers because they run parallel to the long axis of the folia (see Figure 42-4). The spatially polarized dendrites of Purkinje neurons cover extensive terrain in the anterior-posterior direction, but a very narrow territory in the medial-lateral direction. Because the parallel fibers run in the medial-lateral direction, they are oriented perpendicular to the dendritic trees of the Purkinje cells. Thus each granule cell has the potential to form a few synapses with each of a large number of Purkinje neurons, while making denser connections on a few Purkinje neurons as its axon ascends into the molecular layer.

Two Afferent Fiber Systems Encode Information Differently

The two main types of afferent fibers in the cerebellum, the mossy fibers and climbing fibers, both form excitatory synapses with cerebellar neurons but terminate in different layers of the cerebellar cortex, produce different patterns of firing in the Purkinje neurons, and thus probably mediate different functions.

Mossy fibers originate from cell bodies in the spinal cord and brain stem and carry sensory information from the periphery as well as information from the cerebral cortex. They form excitatory synapses on the dendrites of granule cells in the granular layer (Figure 42–5). Each granule cell receives inputs from just a few mossy fibers, but the architecture of the granule cell axons distributes information widely from each mossy fiber to a large number of Purkinje cells. The mossy fiber input is highly convergent; each Purkinje neuron is contacted by axons from somewhere between 200,000 and 1 million granule cells.

Climbing fibers originate in the inferior olivary nucleus and convey sensory information to the cerebellum from both the periphery and the cerebral cortex. The climbing fiber is so named because each enwraps the cell body and proximal dendrites of a Purkinje neuron like a vine on a tree, making numerous synaptic contacts (Figure 42–5). Each climbing fiber contacts 1 to 10 Purkinje neurons, but each Purkinje neuron receives synaptic input from only a single climbing fiber. The terminals of the climbing fibers are arranged topographically in the cerebellar cortex; the axons from clusters of related olivary neurons terminate in thin parasagittal strips that extend across several folia. In turn, the Purkinje neurons within one strip project to a common group of deep nuclear neurons.

The highly specific connectivity of the climbing fiber system contrasts markedly with the massive convergence and divergence of the mossy and parallel fibers, and suggests that the climbing fiber system is specialized for precise control of the electrical activity of Purkinje cells with related functions.

Mossy and climbing fibers have different effects on the electrical activity of Purkinje cells. Climbing fibers have an unusually powerful influence. Each action potential in a climbing fiber generates a protracted, voltage-gated Ca2+ conductance in the soma and dendrites of the postsynaptic Purkinje cell. This results in prolonged depolarization that produces a complex spike: an initial large-amplitude action potential followed by a high-frequency burst of smaller-amplitude action potentials (Figure 42–5). Whether these smaller spikes are transmitted down the Purkinje cell's axon is not clear. In awake animals the climbing fibers spontaneously generate complex spikes at low rates, rarely more than one to three per second. When stimulated they fire single action potentials in temporal relation with specific sensory events.

The climbing-fiber system therefore seems specialized for event detection; the firing rate carries little or no information. Although climbing fibers fire only infrequently, synchronous firing in multiple climbing

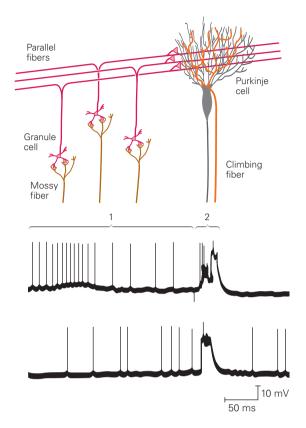

Figure 42–5 Simple and complex spikes recorded intracellularly from a cerebellar Purkinje cell. Simple spikes are produced by mossy fiber input (1), whereas complex spikes are evoked by climbing fiber synapses (2). (Reproduced, with permission, from Martinez, Crill, and Kennedy 1971.)

fibers enables them to signal important events. Synchrony seems to arise partly because neurons in the inferior olivary nucleus often are connected to one another electrotonically.

In contrast, parallel fibers produce only brief, small excitatory potentials in Purkinje neurons. These potentials spread to the initial segment of the axon where they generate simple spikes that propagate down the axon. However, inputs from many parallel fibers are needed to have a substantial effect on the frequency of simple spikes, for each postsynaptic potential is tiny. In awake animals Purkinje neurons emit a steady stream of simple spikes, with spontaneous firing rates as high as 100 per second even when an animal is sitting quietly. Purkinje neurons fire at rates as high as several hundred spikes per second during active eye, arm, and face movements, presumably because of somatosensory, vestibular, and other sensory signals that converge on granule cells through the mossy fibers.

Thus the mossy-fiber system encodes the magnitude and duration of peripheral stimuli or centrally generated behaviors by controlling the firing rate of simple spikes in Purkinje cells.

Parallel Pathways Compare Excitatory and Inhibitory Signals

An important feature of the cerebellar circuit is that excitatory and inhibitory inputs are compared in both the cerebellar cortex and the deep nuclei. In the deep nuclei inhibitory inputs from Purkinje cells converge with excitatory inputs from mossy and climbing fibers (Figure 42–6).

The cerebellum is organized as a series of small, similar modules with close relationships among all the elements of each module. Within a given module a mossy fiber affects target neurons in the deep nuclei

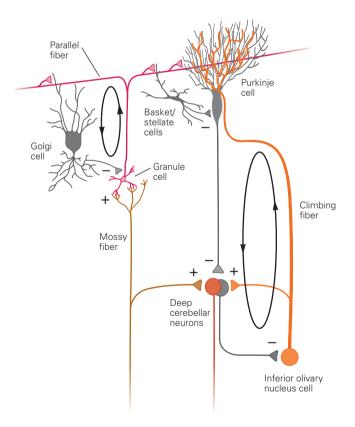

Figure 42–6 Synaptic organization of the cerebellar microcircuit. Excitation and inhibition converge both in the cerebellar cortex and in the deep nuclei. Recurrent loops involve Golgi cells within the cerebellar cortex and the inferior olive outside the cerebellum. (Adapted, with permission, from Raymond, Lisberger, and Mauk 1996.)

in two ways: directly by excitatory synapses and indirectly by pathways through the cortex and the inhibitory Purkinje cells. Thus the inhibitory output of the Purkinje cells modulates or sculpts the excitatory signals transmitted from mossy fibers to the deep nuclei. In almost all parts of the cerebellum the climbing fibers also give off collaterals that excite neurons in the deep nuclei.

In the cerebellar cortex excitatory and inhibitory inputs converge on Purkinje cells. Parallel fibers directly excite Purkinje neurons but also indirectly inhibit them through disynaptic connections from the stellate, basket, and Golgi interneurons. The short axons of stellate cells contact the nearby dendrites of Purkinje cells, whereas the long axons of basket cells run perpendicular to the parallel fibers and form synapses on the Purkinje cell bodies (Figure 42-4). The stellate cells have an inhibitory regulatory effect on the Purkinje cells that is local in that a stellate cell and the Purkinje cell it contacts are both excited by the same parallel fibers. In contrast, the basket cells create flanks of inhibition of Purkinje cells that are excited by flanking beams of parallel fibers other than the central beam that causes the lateral inhibition.

Recurrent Loops Occur at Several Levels

At the broadest level many parts of the cerebellum form recurrent loops with the cerebral cortex. The cerebral cortex projects to the lateral cerebellum through relays in the pontine nuclei. In turn, the lateral cerebellum projects back to the cerebral cortex through relays in the thalamus. This recurrent circuit is organized as a series of parallel closed loops, such that a given part of the cerebral cortex. Figure 42–7 shows how the cerebellum fits into the greater motor circuits from the cerebral cortex to the spinal cord.

Another recurrent loop involves the cerebellum and the inferior olivary nucleus, the source of all climbing fibers. The deep cerebellar nuclei contain GABAergic inhibitory neurons that project to the inferior olive. If inhibitory inputs from the deep nuclei increase then the firing frequency in inferior olive cells decreases, reducing the amount of excitatory climbing fiber input to cerebellar nuclear and Purkinje cells. This provides each part of the cerebellum a way to regulate its own climbing fiber inputs (see Figure 42–6), another in the many checks and balances built into cerebellar circuitry. Interestingly, the GABAergic fibers from the deep nuclei can regulate the electrotonic coupling between olivary neurons. By selectively disconnecting olivary neurons through inhibition, the nervous system

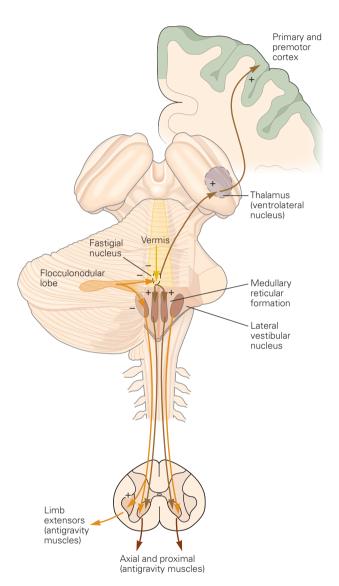

Figure 42–7 The vestibulocerebellum and the vermis control proximal muscles and limb extensors. The vestibulocerebellum (flocculonodular lobe) receives input from the vestibular labyrinth and projects directly to the vestibular nuclei. The vermis receives input from the neck and trunk, the vestibular labyrinth, and retinal and extraocular muscles. Its output is focused on the ventromedial descending systems of the brain stem, mainly the reticulospinal and vestibulospinal tracts and the corticospinal fibers acting on medial motor neurons. The oculomotor connections of the vestibular nuclei have been omitted for clarity.

can activate a specific array of Purkinje neurons synchronously.

The final recurrent loop is contained entirely within the cerebellar cortex and involves Golgi cells. Each Golgi cell receives excitatory inputs from parallel fibers; in turn, its GABAergic terminals provide inhibitory input to the granule cells (Figure 42-6). Golgi cell firing thus suppresses mossy fiber excitation of the granule cells and regulates the firing of the parallel fibers. This loop may shorten the duration of bursts in granule cells. Alternatively, it could limit the magnitude of the excitatory response of granule cells to their mossy fiber inputs. For example, the responses of granule cells could occur only when a certain number of mossy fiber inputs are active, or only when they achieve a threshold frequency of firing. One current idea is that the Golgi cells ensure that only a small number of granule cells are active at any given time, creating a sparse code in the input layer of the cerebellar cortex.

The Vestibulocerebellum Regulates Balance and Eye Movements

The vestibulocerebellum, or flocculonodular lobe, receives information from the semicircular canals and the otolith organs, which sense the head's motion and its position relative to gravity (Figure 42–3). Most of this vestibular input arises from the vestibular nuclei in the brain stem. The vestibulocerebellum also receives mossy fiber visual input, both from pretectal nuclei that lie deep in the midbrain beneath the superior colliculus and from the primary and secondary visual cortex through the pontine and pretectal nuclei.

The vestibulocerebellum is unique in that its output bypasses the deep cerebellar nuclei and proceeds directly to the vestibular nuclei in the brain stem. Purkinje cells in the midline parts of the vestibulocerebellum project to the lateral vestibular nucleus to modulate the lateral and medial vestibulospinal tracts, which predominantly control axial muscles and limb extensors to assure balance during stance and gait. Disruption of these projections through lesions or disease impairs equilibrium.

Purkinje neurons in the lateral parts of the vestibulocerebellum project to the medial vestibular nucleus to control eye movements and coordinate movements of the head and eyes (see Chapter 39). Interestingly, this ancient part of the cerebellum has been co-opted in more recent phylogeny by visual guidance of eye movements. In fact, the most striking deficits following lesions of the lateral vestibulocerebellum are in smooth-pursuit eye movement toward the side of the lesion.

A patient with a lesion of the left lateral vestibulocerebellum can smoothly track a target that is moving to the right, but only poorly tracks motion to the left using predominantly saccades (Figure 42–8A).

Patients with lesions of the lateral vestibulocerebellum have normal ocular responses to head turns, but the responses cannot be suppressed by fixation (Figure 42–8B). If, for example, a patient seated in a barber's chair is rotated to the right in the dark, the vestibuloocular reflex causes smooth eye rotation to the left and resetting saccades to the right. If the patient is placed in the light and views an object attached to the chair, he or she can use fixation to suppress the smooth eye movements of the reflex. For leftward head rotation, however, the patient cannot do so. These deficits occur commonly if the lateral vestibulocerebellum is compressed by an acoustic neuroma, a benign tumor that grows on the eighth cranial nerve as it courses directly beneath the lateral vestibulocerebellum.

The Spinocerebellum Regulates Body and Limb Movements

The spinocerebellum comprises the vermis and intermediate parts of the cerebellar hemispheres (see Figure 42–2A).

Somatosensory Information Reaches the Spinocerebellum Through Direct and Indirect Mossy Fiber Pathways

The spinocerebellum receives extensive sensory input from the spinal cord, mainly from somatosensory receptors conveying information about touch, pressure, and limb position, through several direct and indirect pathways. This input provides the cerebellum with different reports of the changing state of the organism and its environment and permit comparisons between the two.

Direct pathways originate from interneurons in the spinal gray matter and terminate as mossy fibers in the vermis or spinocerebellum. Indirect pathways from the spinal cord to the cerebellum terminate first on neurons in one of several precerebellar nuclei in the brain stem reticular formation: the lateral reticular nucleus, reticularis tegmenti pontis, and paramedian reticular nucleus.

One fundamental principle of cerebellar operation can be appreciated on the basis of two important pathways from the spinal interneurons. The ventral and dorsal spinocerebellar tracts both transmit signals

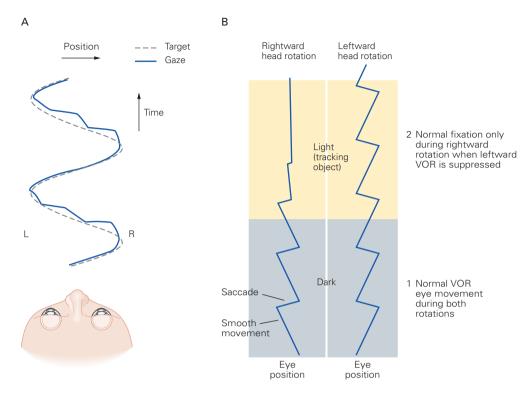

Figure 42–8 Lesions in the vestibulocerebellum have large effects on smooth-pursuit eye movements.

A. Sinusoidal target motion is tracked with smooth-pursuit eye movements as the target moves from left (L) to right (R). With a lesion of the left vestibulocerebellum, smooth pursuit is punctuated by saccades when the target moves from right to left.

B. In the same patient responses to vestibular stimulation are normal, whereas object fixation is disrupted during leftward rotation. Each trace shows the eye movements evoked by head rotation while the patient fixates on a target that moves

along with him, first in the dark and then in the light. (1) In the dark the eyes show a normal vestibulo-ocular reflex (VOR) during rotation in both directions: The eyes move smoothly in the direction opposite to the head's rotation, then reset with saccades in the direction of head rotation. (2) In the light the eye position during rightward head rotation is normal: Fixation on the target is excellent and the vestibulo-ocular reflex is suppressed. During leftward head rotation, however, the subject is unable to fixate on the object and the vestibulo-ocular reflex cannot be suppressed.

from the spinal cord directly to the cerebellar cortex but convey two different kinds of information.

The *dorsal spinocerebellar tract* conveys somatosensory information from muscle and joint receptors, providing the cerebellum with sensory feedback about the consequences of the movement. This information flows whether the limbs are moved passively or voluntarily.

In contrast, the *ventral spinocerebellar tract* is active only during active movements. Its cells of origin receive the same inputs as spinal motor neurons and interneurons, and it transmits an efference copy or corollary discharge of spinal motor neuron activity that informs the cerebellum about the movement commands assembled at the spinal cord. The cerebellum is thought to compare this information on planned movement with the actual movement reported by the dorsal spinocerebellar tract

in order to determine whether the motor command must be modified to achieve the desired movement. The dorsal and ventral spinocerebellar tracts provide inputs from the hind limbs, whereas the cuneocerebellar and rostral spinocerebellar tracts provide similar inputs from more rostral body parts.

The idea that the cerebellum compares the actual and expected sensory consequences of movements is supported by studies of a number of movement systems. As a decerebrated cat walks on a treadmill, for example, the firing rate of neurons in the dorsal and ventral spinocerebellar tracts is rhythmically modulated in phase with the step cycle. However, when the dorsal roots are cut, preventing spinal neurons from receiving peripheral inputs that modulate with the step cycle, neurons of the dorsal spinocerebellar tract

fall silent, whereas the firing of neurons of the ventral spinocerebellar tract continues to be modulated.

Recordings from the vestibulocerebellum of monkeys show that Purkinje neurons compare vestibular sensory inputs related to head velocity with corollary inputs related to eye velocity. The simple-spike output from these Purkinje neurons is modulated only when the eye movements are different from those expected from the vestibulo-ocular reflex. The cerebellum participates in the control of smooth eye movement only when the brain stem reflex pathways alone cannot produce the desired motor outputs.

The Spinocerebellum Modulates the Descending Motor Systems

Purkinje neurons in the spinocerebellum project somatotopically to different deep nuclei that control various components of the descending motor pathways. Neurons in the vermis of both the anterior and posterior lobes send axons to the fastigial nucleus. The fastigial nucleus projects bilaterally to the brain stem reticular formation and lateral vestibular nuclei, which in turn project directly to the spinal cord (Figure 42–7).

The spinocerebellum therefore provides important inputs to the brain stem components of the medial descending systems. Its outputs are important for movements of the neck, trunk, and proximal parts of the arm, rather than the wrist and digits, for balance and postural control during voluntary motor tasks. Because these brain stem systems also receive large inputs from descending pathways and from sensory inputs, we think that the cerebellum modulates and initiates, rather than controls, the descending commands to the spinal cord.

Purkinje neurons in the intermediate part of the cerebellar hemispheres project to the interposed nucleus. Some axons of the interposed nucleus exit through the superior cerebellar peduncle and cross to the contralateral side of the brain to terminate in the magnocellular portion of the red nucleus. Axons from the red nucleus cross the midline again and descend to the spinal cord (Figure 42–9). Other axons from the interposed nucleus continue rostrally and terminate in the ventrolateral nucleus of the thalamus. Neurons in the ventrolateral nucleus project to the limb control areas of the primary motor cortex.

By acting on the neurons that give rise to the rubrospinal and corticospinal systems, the intermediate cerebellum focuses its action on limb and axial musculature. Because cerebellar outputs cross the midline twice before reaching the spinal cord, cerebellar lesions disrupt ipsilateral limb movements.

The Vermis Controls Saccadic and Smooth-Pursuit Eye Movements

The vermis is involved in the control of saccades and smooth-pursuit eye movements through Purkinje cells in lobules V, VI, and VII (Figure 42–2C). The cells discharge prior to and during such movements, and lesions of these areas cause deficits in the accuracy of both kinds of movements.

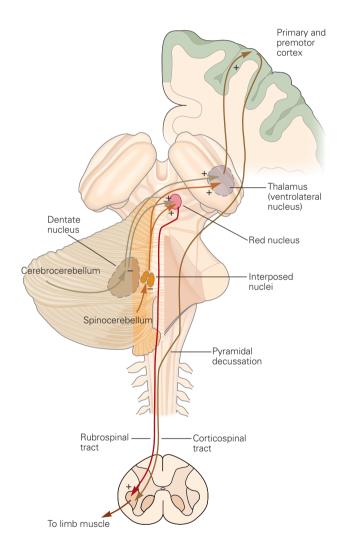

Figure 42–9 Neurons in the intermediate and lateral parts of the cerebellar hemispheres control limb and axial muscles. The intermediate part of each hemisphere (spinocerebellum) receives sensory information from the limbs and controls the dorsolateral descending systems (rubrospinal and corticospinal tracts) acting on the ipsilateral limbs. The lateral area of each hemisphere (cerebrocerebellum) receives cortical input via the pontine nuclei and influences the motor and premotor cortices via the ventrolateral nucleus of the thalamus.

The vermis may be the only area of the cerebellum responsible for saccades, but it seems to share responsibility for smooth pursuit with the lateral part of the flocculonodular lobe. The outputs from neurons of the vermis concerned with saccades are transmitted through a very small region of the caudal fastigial nucleus to the saccade generator in the reticular formation. The exact neural pathways for guidance of pursuit by the vermis are not known, but they involve more synaptic relays than the outputs from the lateral part of the flocculonodular lobe, which reach extraocular motor neurons through two intervening synapses. One idea currently being explored is that the vermis also plays a role in motor learning that corrects errors in saccades and smooth-pursuit movements.

Spinocerebellar Regulation of Movement Follows Three Organizational Principles

In addition to confirming that cerebellar lesions in animals have the same effects as in humans, animal studies have provided an initial understanding of what the cerebellum does in healthy people and why lesions of the cerebellum have the effects they do.

Many experiments using monkeys have recorded the action potentials of single neurons in the interposed and dentate nuclei and the intermediate and lateral cerebellar cortex during arm movements. Other experiments have used cooling probes or substances that temporarily inactivate neurons to compare specific aspects of motor behavior in an active and inactive cerebellum. From these experiments we can draw three basic conclusions regarding the function of the spinocerebellum.

First, both Purkinje neurons and deep cerebellar nucleus neurons discharge vigorously in relation to voluntary movements. Cerebellar output is related to the direction and speed of movement. The deep nuclei are somatopically organized into maps of different limbs and joints, as in the motor cortex. Moreover, the interval between the onset of modulation of the firing of cerebellar neurons and movement is remarkably similar to that for neurons in the motor cortex. This result emphasizes the cerebellum's participation in recurrent circuits that operate synchronously with the cerebral cortex.

Second, the cerebellum provides feed-forward control of muscle contractions to regulate the timing of movements. Rather than awaiting sensory feedback, cerebellar output anticipates the muscular contractions that will be needed to bring a movement smoothly, accurately, and quickly to its desired endpoint. Failure of these mechanisms causes the intention tremor of cerebellar disorders.

Normally a rapid single-joint movement is initiated by the contraction of an agonist muscle and terminated

by an appropriately timed contraction of the antagonist. The contraction of the antagonist starts early in the movement, well before there has been time for sensory feedback to reach the brain, and therefore must be programmed as part of the movement. When the dentate and interposed nuclei are experimentally inactivated, however, contraction of the antagonist muscle is delayed until the limb has overshot its target. The programmed contraction seen in normal movements is replaced by a feedback correction driven by sensory input. This correction is itself dysmetric and results in another error, necessitating a new adjustment (Figure 42–10).

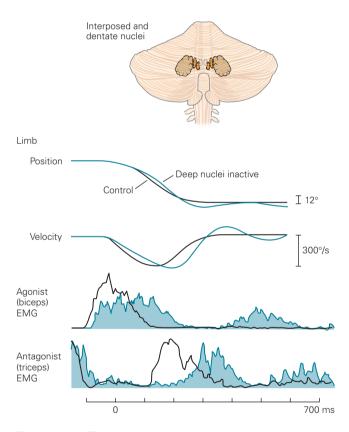

Figure 42–10 The interposed and dentate nuclei are involved in the precise timing of agonist and antagonist activation during rapid movements. The records show arm position and velocity and electromyographic responses of the biceps and triceps muscles of a trained monkey during a rapid movement. When the deep nuclei are inactivated by cooling, activation of the agonist (biceps) becomes slower and more prolonged. Activation of the antagonist (triceps), which is needed to stop the movement at the correct location, is likewise delayed and protracted so that the initial movement overshoots its appropriate extent. Delays in successive phases of the movement produce oscillations similar to the terminal tremor seen in patients with cerebellar damage.

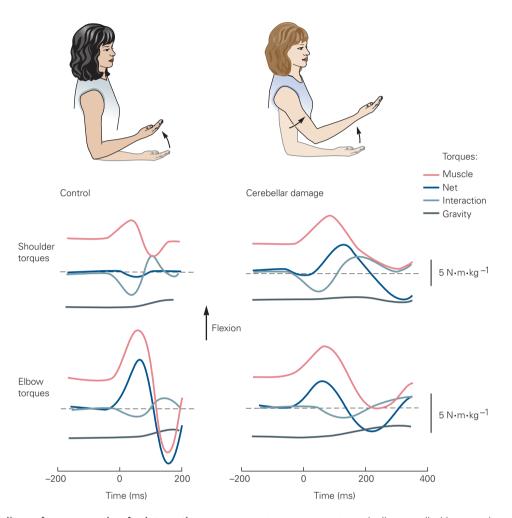

Figure 42–11 Failure of compensation for interaction torques can account for cerebellar ataxia. Subjects flex their elbows while keeping their shoulder stable. In both the control subject and the cerebellar patient the net elbow torque is large because the elbow is moved. In the control subject there is relatively little net shoulder torque because the interaction

torques are automatically cancelled by muscle torques. In the cerebellar patient this compensation fails; the muscle torques are present but are inappropriate to cancel the interaction torques. As a result, the patient cannot flex her elbow without causing a large perturbation of her shoulder position. (Adapted, with permission, from Bastian, Zackowski, and Thach 2000.)

Third, the cerebellum has internal models of the limbs that automatically take account of limb structure. (See Chapter 33 for a discussion of internal models.) An accurate dynamic model of the arm, for example, can convert a desired final endpoint into a sequence of properly timed and scaled commands for muscular contraction. At the same time, an accurate kinematic model of the relationship between joint angles and finger position can specify the joint angles that are needed to achieve an endpoint. Recordings of the output of the cerebellum have provided evidence compatible with the idea that the cerebellum contains kinematic and dynamic models of both arm and eye movements.

Studies of the movements of patients with cerebellar disorders suggest that the interaction torques of a multi-segment limb are represented by an internal model in the cerebellum. Because of the structure of the arm and the momentum it develops when moving, movement of the forearm alone causes forces that move the upper arm. If a subject wants to flex or extend the elbow without simultaneously moving the shoulder, then muscles acting at the shoulder must contract to prevent its movement. These stabilizing contractions of the shoulder joint occur almost perfectly in control subjects but not in patients with cerebellar damage (Figure 42–11). Patients with cerebellar ataxia are unable to compensate for interaction torques.

They experience difficulty controlling the inertial interactions among multiple segments of a limb accounts and greater inaccuracy of multi-joint versus singlejoint movements.

In conclusion, the cerebellum uses internal models to anticipate the forces that result from the mechanical properties of a moving limb and may use its learning capabilities to customize internal models to anticipate those forces accurately.

Recent research suggests that excessive variability of Purkinje-cell output can lead to ataxia, suggesting that the regularity of cerebellar activity must be closely regulated to achieve normal movement. In animal models cerebellar symptoms result when deletion of certain ion channels causes the firing of Purkinje cells to become excessively variable even though the mean firing rate is entirely normal when averaged across many repetitions of a movement.

Are the Parallel Fibers a Mechanism for Motor Coordination?

A conspicuous feature of cerebellar structure is the medial-lateral parallel fiber "beam." Parallel fibers extend up to 6 mm through the molecular layer and excite the dendrites of Purkinje, basket, stellate, and Golgi cells along their course (see Figure 42–4). Basket and stellate axons create inhibitory flanks along the sides of the parallel fiber beam.

One current idea is that the great extent of the parallel fibers allows them to tie together the activity of different cerebellar compartments. Purkinje cells project topographically onto the deep cerebellar nuclei, each of which contains a complete map of body parts and muscles. In each map the representation of the tail is located anteriorly and that of the head posteriorly, with the limbs medially and the trunk laterally. The long trajectory of the parallel fibers could link different body parts in a medial-lateral dimension in different combinations.

In rats trained to reach to a target, for example, Purkinje cells along the medial-lateral parallel fiber beam fire simple spikes simultaneously and in precise synchrony with the movement. Pairs of Purkinje cells that are not situated along the same excitatory beam show no such synchrony. The synchrony may link muscles for multi-muscle movements and synchronize their contractions.

Finally, sagittal splitting of the posterior vermis in children, an operation performed to remove tumors in the fourth ventricle, creates surprisingly little functional deficit. The children can walk and climb

stairs without assistance or obvious abnormality, and they can hop on one leg repeatedly almost as well as healthy children. Nevertheless, a striking deficit occurs when they attempt heel-to-toe tandem gait. Without support they fall after three steps. The discrepancy between the large deficit in tandem gait and the normal one-legged hopping is striking because both require the integration of vestibular, somesthetic, and visual sensation. These observations imply that the severed parallel fibers crossing in the vermis are essential to coordination of the projections to the bilateral fastigial nuclei.

The Cerebrocerebellum Is Involved in Planning Movement

The Cerebrocerebellum Is Part of a High-Level Internal Feedback Circuit That Plans Movement and Regulates Cortical Motor Programs

Clinical observations by neurologists and neurosurgeons initially suggested that, like the rest of the cerebellum, the lateral hemispheres (the cerebrocerebellum) are primarily concerned with motor function. However, recent clinical and experimental studies indicate that the lateral hemispheres in humans also have perceptual and cognitive functions. Indeed, the lateral hemispheres are much larger in humans than in monkeys, just as in humans the frontal regions of the cerebral cortex are greatly expanded.

In contrast to other regions of the cerebellum, which receive sensory information more directly from the spinal cord, the lateral hemispheres receive input exclusively from the cerebral cortex. This cortical input is transmitted through the pontine nuclei and through the middle cerebellar peduncle to the contralateral dentate nucleus and lateral hemisphere (see Figure 42–3).

Purkinje neurons in the lateral hemisphere project to the dentate nucleus. Most dentate axons exit the cerebellum through the superior cerebellar peduncle and terminate in two main sites. One terminus is an area of the contralateral ventrolateral thalamus that also receives input from the interposed nucleus. These thalamic cells project to premotor and primary motor cortex (see Figure 42–9).

The second principal terminus of dentate neurons is the contralateral red nucleus, specifically a portion of the parvocellular area of the nucleus distinct from that which receives input from the interposed nucleus. These neurons project to the inferior olivary nucleus,

which in turn projects back to the contralateral cerebellum as climbing fibers, thus forming a recurrent loop (see Figure 42–6). Neurons in the parvocellular portion of the red nucleus, in addition to receiving input from the dentate nucleus, also receive input from the lateral premotor areas. On the basis of brain imaging, the intriguing suggestion has been made that this loop involving the premotor cortex, lateral cerebellum, and rubrocerebellar tract participates in the mental rehearsal of movements and perhaps in motor learning (see Chapter 33).

Lesions of the Cerebrocerebellum Disrupt Motor Planning and Prolong Reaction Time

In the first half of the 20th century, neurologists identified two characteristic motor disturbances in patients with localized damage in the cerebrocerebellum: variable delays in initiating movements and irregularities in the timing of movement components. The same defects are seen in primates with lesions of the dentate nucleus.

Clinical observations suggest that the cerebrocerebellum has a role in the planning and programming of hand movements, and recordings of the activity of neurons in the dentate nucleus in primates support this idea. Some neurons in the dentate nucleus fire some 100 ms before a movement begins and even before the discharge of neurons in either the primary motor cortex or interposed nuclei, which are more directly concerned with the execution of movement. The onset of firing in the primary motor cortex, and thus the onset of movement, can be delayed experimentally by inactivating the dentate nucleus (Figure 42–10). Nevertheless, movement is simply delayed, not prevented, demonstrating that the dentate nucleus is not absolutely necessary for the initiation of movement.

The Cerebrocerebellum May Have Cognitive Functions Unconnected with Motor Control

When patients with cerebellar lesions attempt to make regular tapping movements with their hands or fingers, the rhythm is irregular, and the motions are variable in duration and force. Based on a theoretical model of how tapping movements are generated, Richard Ivry and Steven Keele inferred that medial cerebellar lesions interfere only with accurate execution of the response, whereas lateral cerebellar lesions interfere with the timing of serial events. This timing defect was not limited to motor events. It also affected the patient's ability to judge elapsed time in purely mental or

cognitive tasks, as in the ability to distinguish whether one tone was longer or shorter than another or whether the speed of one moving object was greater or less than that of another.

This demonstration that the cerebellum is responsible for a cognitive computation independent of motor execution prompted other researchers to investigate purely cognitive functions of the cerebellum. For example, Steve Petersen, Julie Fiez, and Marcus Raichle used positron emission tomography to image the brain activity of people during silent reading, reading aloud, and speech. As expected, areas of the cerebellum involved in the control of mouth movements were more active when subjects read aloud than when they read silently.

In a task with greater cognitive load subjects were asked to name a verb associated with a noun; a subject might respond with "bark" if he or she saw the word "dog." Compared with simply reading aloud, the word-association task produced a pronounced increase in activity within the right lateral cerebellum. In agreement with this study, a patient with damage in the right cerebellum could not learn a word-association task.

Functional magnetic resonance imaging provides evidence that the lateral cerebellum has a role in other cognitive activities. For example, solving a pegboard puzzle involves greater activity in the dentate nucleus and lateral cerebellum than does the simple motor task of moving the pegs on the board. Interestingly, the active area of the dentate nucleus is the area that receives input from the part of the cerebral cortex (area 46) involved in working memory. The dentate nucleus appears to be particularly important in processing sensory information for tasks that require complex spatial and temporal judgments, which are essential for complex motor actions and sequences of movements.

The Cerebellum Participates in Motor Learning

Climbing-Fiber Activity Produces Long-Lasting Effects on the Synaptic Efficacy of Parallel Fibers

On the basis of mathematical modeling of cerebellar function and the striking features of the cerebellar microcircuit described earlier in the chapter, David Marr and James Albus independently suggested in the early 1970s that the cerebellum might be involved in learning motor skills. Along with Masao Ito, they proposed that the climbing-fiber input to Purkinje neurons modifies the response of the neurons to mossyfiber inputs and does so for a prolonged period of time.

Subsequent experimental evidence has supported the theory. Despite the low frequency of their discharge, climbing fibers modulate the input of parallel fibers to Purkinje cells. In particular, climbing fibers can selectively induce *long-term depression* in the synapses between Purkinje neurons and parallel fibers that are activated concurrently with the climbing fibers. Long-term depression has been analyzed in slices and cultures of cerebellum, where it is possible

to record the postsynaptic potentials of Purkinje cells following stimulation of climbing fibers and parallel fibers. Many studies have found that concurrent stimulation of climbing fibers and parallel fibers depresses the Purkinje cell responses to subsequent stimulation of the same parallel fibers but not to stimulation of parallel fibers that had not been stimulated earlier along with climbing fibers (Figure 42–12A). The resulting depression can last for minutes to hours.

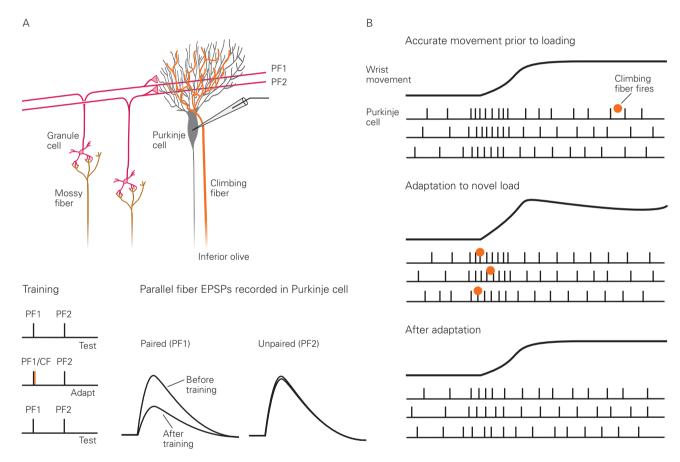

Figure 42–12 Long-term depression of the synaptic input from parallel fibers to Purkinje cells is one plausible mechanism for cerebellar learning.

A. Two different groups of parallel fibers and the presynaptic climbing fibers are electrically stimulated in vitro. Repeated stimulation of one set of parallel fibers (PF1) at the same time as the climbing fibers produces a long-term reduction in the responses of those parallel fibers to later stimulation. The responses of a second set of parallel fibers (PF2) are not depressed because they are not stimulated simultaneously with the presynaptic climbing fibers. (CF, climbing fiber; EPSP, excitatory postsynaptic potential.) (Adapted, with permission, from Ito et al. 1982.)

B. Top: An accurate wrist movement by a monkey is accompanied by a burst of simple spikes in a Purkinje cell, followed later by discharge of a single climbing fiber in one trial. Middle: When the monkey must make the same movement against a novel resistance (adaptation), climbing-fiber activity occurs during movement in every trial and the movement itself overshoots the target. Bottom: After adaptation the frequency of simple spikes during movement is quite attenuated, and the climbing fiber is not active during movement or later. This is the sequence of events expected if long-term depression in the cerebellar cortex plays a role in learning. Climbing fiber activity is usually low (1/s) but increases during adaptation to a novel load. (Adapted, with permission, from Gilbert and Thach 1977.)

What functional effects might this long-term depression have? According to the theories of Marr and Albus, altering the strength of certain synapses between parallel fibers and Purkinje cells shapes or corrects eye and limb movements. During an inaccurate movement the climbing fibers respond to specific movement errors and depress the synaptic strength of parallel fibers involved with those errors, namely those that had been activated with the climbing fiber (Figure 42–12B). With successive movements the parallel fiber inputs conveying the flawed central command are increasingly suppressed, a more appropriate pattern of simple-spike activity emerges, and eventually the climbing-fiber error signal disappears.

Learning Occurs at Multiple Sites in the Cerebellar Microcircuit

Initial studies of cerebellar learning focused on the vestibulo-ocular reflex, a coordinated response that keeps the eyes fixed on a target when the head is rotated (see Chapter 40). Motion of the head in one direction is sensed by the vestibular labyrinth, which initiates eye movements in the opposite direction to maintain the image in the same position on the retina.

When humans and experimental animals wear glasses that change the size of a visual scene, the vestibulo-ocular reflex initially fails to keep images stable on the retina because the amplitude of the reflex is inappropriate to the new conditions. After the glasses have been worn continuously for several days, however, the size of the reflex becomes progressively reduced (for miniaturizing glasses) or increased (for magnifying glasses). Adaptation of the vestibulo-ocular reflex can be blocked in experimental animals by lesions of the lateral part of the vestibulocerebellum, indicating that the cerebellum also has an important role in this form of learning, as discussed below.

Classical conditioning of the eye-blink response also depends on an intact cerebellum. In this form of associative learning a neutral stimulus such as a tone is played while a puff of air is directed at the cornea, causing the eye to blink just before the end of the tone. If this paradigm is repeated many times, the brain learns the tone's predictive power and the tone alone is sufficient to cause a blink. Michael Mauk and his colleagues have shown that the brain also can learn about the timing of the stimulus so that the eye blink occurs at the right time. It is even possible to learn to blink at different times in response to tones of different frequencies.

The cerebellum is also involved in learning limb movements that depend on eye-hand coordination.

Adaptation of such movements can be demonstrated by having people wear prisms that deflect the light path sideways. When a person plays darts while wearing prisms that displace the entire visual field to the right, the initial dart throw lands to the left side of the target by an amount proportional to the strength of the prism. The subject gradually adapts to the distortion through practice, so that the darts land on target within 10 to 30 throws (Figure 42–13). When the prisms are removed, the adaptation persists, and the darts hit the right side of the target by roughly the same distance as the initial prism-induced error. Patients with a damaged cerebellar cortex or inferior olive are severely impaired or unable to adapt at all in this task.

Extensive analysis of the cerebellum during adaptation of the vestibulo-ocular reflex, classical conditioning of the eye-blink response, and voluntary arm movements has led to a coherent theory about the cerebellum's role in motor learning. Learning occurs not only in the cerebellar cortex, as postulated by Marr, Albus, and Ito, but also in the deep cerebellar nuclei (Figure 42–14). Available evidence is compatible with the long-standing suggestion that inputs from climbing fibers provide instructive signals that lead to changes in synaptic strength within the cerebellar cortex.

The original hypothesis of learning in the cerebellum focused on long-term depression of the synapses from parallel fibers to Purkinje cells, one of a group of possible sites where climbing fibers cause plasticity. But there are additional sites of synaptic and cellular plasticity throughout the microcircuit, notably in the deep cerebellar nuclei. Learning seems to be implemented through complementary synaptic changes in the cerebellar cortex and deep nuclei. The cerebellum appears to be the learning machine envisioned by the earliest investigators, but its learning capabilities may be even greater and more widely localized than imagined.

As outlined in Chapter 33 and earlier in this chapter, many operations performed by the motor system may be based on internal models. If the brain has accurate internal models of the dynamics and kinematics of the arm, for example, then it can compute signals that generate accurate movements. Synaptic plasticity could be the mechanism that creates and maintains accurate internal models. One important function of learning in the cerebellum may be to provide continuous tuning of internal models in the cerebellum. By using sensory feedback to adjust synaptic and cellular function, cerebellar internal models can be tuned to create commands for movements that are rapid, accurate, and smooth.

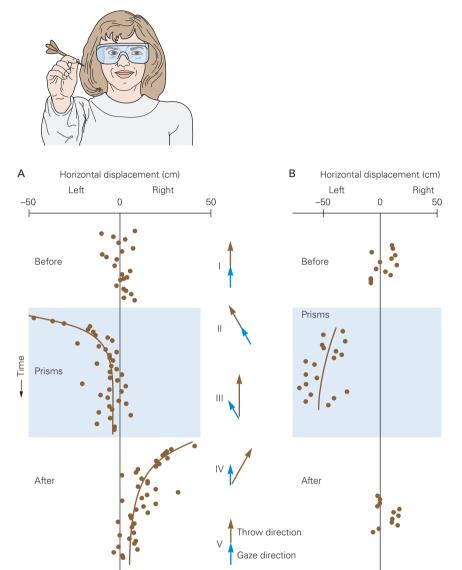

Figure 42–13 Adjustment of eye-hand coordination to a change in optical conditions. The subject wears prisms that bend the optic path to her right. She must look to her left along the bent light path to see the target directly ahead. (Adapted, with permission, from Martin et al. 1996a, 1996b.)

A. Without prisms the subject throws with good accuracy. The first hit after the prisms have been put in place is displaced left of center because the hand throws where the eyes are directed. Thereafter hits trend rightward toward the target, away from where the eyes are looking. After removal of the prisms the subject fixes her gaze in the center of the target; the first throw hits to the right of center, away from where the eyes are directed. Thereafter hits trend toward the target. Data during and after prism use have been fit with exponential curves. Gaze and throw directions are indicated by the blue and brown arrows, respectively, on the right. The inferred gaze direction assumes that the subject is fixating the target.

Before donning the prisms the subject looks at and throws toward the target (I). Just after donning prisms, when her gaze is directed along the bent light path away from the target, she throws in the direction of gaze, away from the target (II). After adapting to the prisms she directs her gaze along the bent light path away from the target but directs her throw toward the target (III). Immediately after removing the prisms she directs her gaze toward the target; her adapted throw is to the right of the direction of gaze and to the right of the target (IV). After recovery from adaptation she again looks at and throws toward the target (V).

B. Adaptation fails in a patient with unilateral infarctions in the territory of the posterior inferior cerebellar artery that involve the inferior cerebellar peduncle and inferior lateral posterior cerebellar cortex.

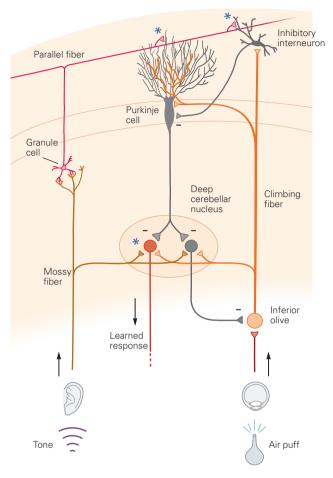

Figure 42–14 Learning can occur in the cerebellar microcircuit both in the cerebellar cortex and in the deep cerebellar nuclei. The diagram is based on classical conditioning of the eyelid response (combining a tone and air puff), but describes equally well adaptation of the vestibulo-ocular reflex when head turns are associated with image motion on the retina (see Chapter 40). Sites of learning are denoted by asterisks. (Adapted, with permission, from Carey and Lisberger 2002.)

An Overall View

Whereas lesions of other motor processing centers result in paralysis of voluntary movements, lesions of the cerebellum result in large errors in movements. How do these errors occur?

The organization of the inputs and outputs of the cerebellum indicates that the cerebellum compares internal feedback signals that report the intended movement with external feedback signals that report the actual motion. On a very short time scale during the execution of the movement, the cerebellum is able to generate corrective signals that help to make

movements accurate. These corrective signals are feedforward or anticipatory actions that operate on the descending motor systems of the brain stem and cerebral cortex. When these mechanisms fail because of lesions of the cerebellum, movement develops characteristic oscillations and tremors.

The corrective control of movement by the cerebellum is complemented by important cerebellar contributions to motor learning. Although some aspects of a movement can be adjusted "on-the-fly" during the movement, much about the movement must be well planned in advance, and planning necessarily incorporates adjustments of motor programs based on learning. The cerebellum may have a role in motor learning through the ability of the climbing fibers to depress activity in the parallel fibers. Because of their low firing frequencies, climbing fibers have only a modest capacity for transmitting moment-to-moment changes in sensory information. Instead, they may be involved in detecting error in a movement and changing the program for the next movement.

Finally, the cerebellum seems to have a role in some purely mental operations. In many respects these operations appear to be similar to the cerebellum's motor functions. For example, the different regions of the lateral hemisphere appear to be particularly important for forms of both motor and cognitive learning that depend on repeated practice.

Abnormal Neuronal Activity in Nonmotor Circuits Is Associated with Several Neuropsychiatric Disorders

An Overall View

THE TRADITIONAL VIEW THAT THE BASAL ganglia play a role in movement stems largely from the fact that diseases of the basal ganglia, such as Parkinson and Huntington disease, are associated with

prominent disturbances of movement and from the earlier belief that basal ganglia neurons send their output exclusively to the motor cortex by way of the thalamus. However, we now know that the basal ganglia also project to nonmotor areas of the cerebral cortex, providing a mechanism whereby they may participate in a wide variety of nonmotor functions, and that diseases of the basal ganglia are associated with complex behavioral and neuropsychiatric disturbances.

In this chapter we first describe the individual nuclei of the basal ganglia anatomically and then discuss their function in the context of the larger networks in which they participate. The delineation of brain circuits into which the basal ganglia are incorporated has enabled researchers to better understand the pathophysiology of some of the major diseases affecting basal ganglia functions. These disease states are described at the end of the chapter.

The Basal Ganglia Consist of Several Interconnected Nuclei

The basal ganglia comprise four principal structures: the striatum, globus pallidus, substantia nigra, and subthalamic nucleus (Figure 43–1).

The *striatum* is separated by the internal capsule into the caudate nucleus and the putamen. The striatum is the major input structure of the basal ganglia, receiving prominent projections from the cerebral cortex, brain stem, and thalamus. The *globus pallidus* consists of two separate nuclei, the external and internal segments, each with different connectivity and

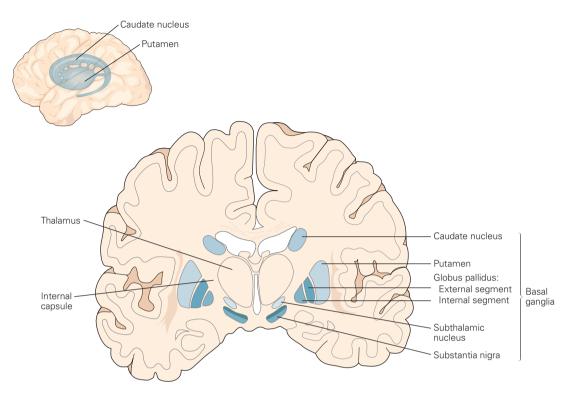

Figure 43–1 The basal ganglia and surrounding structures. The nuclei of the basal ganglia are identified on right in this

coronal section. (Adapted, with permission, from Nieuwenhuys, Voogd, and van Huijzen 1981.)

functions. The internal segment is one of the major output structures of the basal ganglia, whereas the external segment is part of their intrinsic circuitry.

The *substantia nigra* includes two separate nuclei, the pars compacta and pars reticulata. Along with portions of the ventral tegmental area and other midbrain areas, the pars compacta, or mediodorsal portion of the substantia nigra, contains dopaminergic cells that project heavily to the striatum and to the other nuclei of the basal ganglia. The pars reticulata, or ventrolateral portion of the substantia nigra, is the other major output nucleus of the basal ganglia. In fact, the pars reticulata of the substantia nigra and the internal segment of the globus pallidus can be viewed as a single output structure divided by the internal capsule.

The fourth principal structure of the basal ganglia, the *subthalamic nucleus*, is a small nucleus situated between the thalamus and the substantia nigra. This nucleus receives projections from the external segment of the globus pallidus, the cerebral cortex, thalamus, and brain stem, and sends output to both segments of the globus pallidus and to the substantia nigra pars reticulata. The cortical inputs to the

subthalamic nucleus and the related subthalamopallidal projections are referred to as the *hyperdirect* pathway (Figure 43–2).

The striatum, the main input nucleus of the basal ganglia, projects to the two basal ganglia output nuclei, the internal pallidal segment and the substantia nigra pars reticulata. The axons from the striatum follow two different pathways: a *direct* monosynaptic connection, and an *indirect* polysynaptic pathway that passes first to the external pallidal segment and from there to both output nuclei, either directly or via the intercalated subthalamic nucleus.

The output nuclei project to specific thalamic and brain stem areas. Projections to the thalamus are directed to the ventral anterior, the ventrolateral, and the intralaminar nuclei. Thalamic projections to the frontal lobe then transmit the output of the basal ganglia to the same areas of frontal cortex that provide input to the basal ganglia. In addition, descending pallidal and nigral projections to the brain stem, such as those to the pedunculopontine nucleus and superior colliculus, provide pathways by which the basal ganglia may directly influence brain stem and spinal

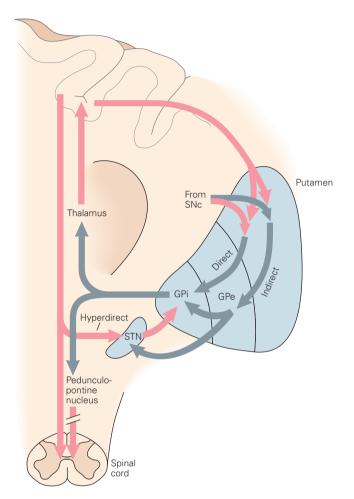

Figure 43–2 The basal ganglia—thalamocortical circuitry. The circuitry of the basal ganglia includes the striatum (here represented by one of its components, the putamen), the external and internal segments of the globus pallidus (GPe and GPi, respectively), the substantia nigra pars reticulata (not shown) and pars compacta (SNc), and the subthalamic nucleus (STN). Cortical input enters the striatum and subthalamic nucleus. Basal ganglia output is conveyed to several thalamic nuclei (the centromedian and parafascicular nuclei and the ventral anterior and ventral lateral nuclei) and the pedunculopontine nucleus. Excitatory connections are shown in red, inhibitory pathways in gray. The dopaminergic SNc projection to the striatum regulates corticostriatal transmission along direct and indirect pathways.

motor circuits, especially those related to gait and balance. The brain stem nuclei may integrate basal ganglia inputs with cerebellar inputs. The pedunculopontine nucleus is part of several feedback circuits through its projections back to the basal ganglia and thalamus. Output of the substantia nigra pars reticulata is also directed to the superior colliculus, which is involved in the control of head and eye movements.

In the striatum the most common neuronal cell type is the GABAergic (γ -aminobutyric acid) medium spiny neuron. These cells are so named because of the abundance of spines on their dendrites. They receive inputs from the cerebral cortex and thalamus as well as from several classes of local interneurons in the striatum, including large cholinergic interneurons and smaller GABAergic interneurons.

The activities of medium spiny neurons are modulated by other neurotransmitters, specifically inputs from dopaminergic neurons in the substantia nigra pars compacta and the ventral tegmental area. Some of the dopaminergic fibers terminate on the necks of dendritic spines of medium spiny neurons, where they are in a position to influence corticostriatal transmission (Figure 43–3). Dopamine released from terminals close to the dendritic spines may have similar effects through spillover and diffusion of the neurotransmitter.

The cytoarchitecture of the other basal ganglia nuclei is distinctly different from that of the striatum. Both segments of the globus pallidus consist of large GABAergic neurons that receive input from the striatum. The substantia nigra pars reticulata is histologically similar to the internal pallidal segment, containing GABAergic neurons that interdigitate with the more dorsal dopaminergic cells of the substantia nigra pars compacta. The subthalamic nucleus is a densely packed structure whose projection neurons, unlike those in the other basal ganglia nuclei, are glutamatergic.

A Family of Cortico-Basal Ganglia-Thalamocortical Circuits Subserves Skeletomotor, Oculomotor, Associative, and Limbic Functions

Areas of the cerebral cortex project in a highly topographic manner onto the striatum.

The topographic termination pattern establishes functional domains that are replicated throughout the basal ganglia–thalamocortical circuits by virtue of highly topographic projections at each synaptic relay. The different pathways that pass through the basal ganglia are named after the presumed functions of the regions of the frontal cortex from which they originate: the skeletomotor, oculomotor, prefrontal (associative), and limbic circuits. The frontal lobe origins of these circuits in the cerebral cortex are shown in Figure 43–4 and the synaptic relays are depicted in Figure 43–5.

Additional projections from the parietal, temporal, and occipital lobes that are reciprocally interconnected with the frontal areas converge onto the same areas in the striatum. Importantly, however, although

each circuit receives both pre- and postcentral cortical inputs, output of the different circuits terminates only in the frontal lobe areas of their respective origin.

Ascending output in each functional pathway is projected in a somatotopical manner to the thalamus and from there to the frontal cortical area from which the circuit originated, thus partially closing a system of cortico-subcortical loops. The subcortical segregation of the functionally distinct circuits may allow different aspects of behavior to be processed in parallel.

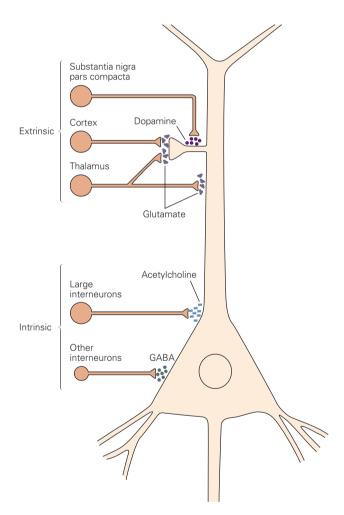

Figure 43–3 The medium spiny neurons in the striatum have extrinsic and intrinsic inputs. Glutamatergic inputs from the cerebral cortex and dopaminergic inputs from the substantia nigra pars compacta terminate on dendritic spines of medium spiny neurons. The reward-related dopaminergic inputs are thought to modulate the strength of cortical inputs and to play a role in synaptic changes and reinforcement learning in the striatum. Glutamatergic inputs from the thalamus end on the spines and shafts of dendrites of medium spiny neurons. Medium spiny neurons also receive cholinergic and GABAergic input from interneurons in the striatum.

The Cortico-Basal Ganglia-Thalamocortical Motor Circuit Originates and Terminates in Cortical Areas Related to Movement

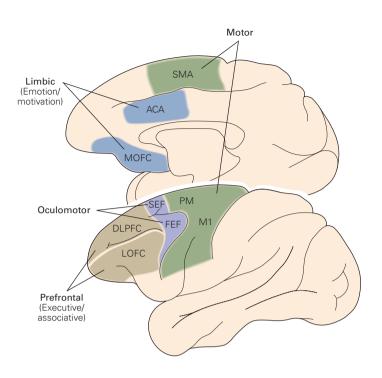

Most of our knowledge about the anatomy and physiological functions of the basal ganglia—thalamocortical circuits comes from studies of the motor circuit. This circuit has attracted the attention of researchers because pathology within its anatomical elements has been implicated in several major disorders of movement.

The motor circuit originates in the pre- and postcentral sensorimotor cortical fields, which project to the putamen in a somatotopical manner. This arrangement has been demonstrated not only with anatomical methods but also with electrophysiological recordings of neuronal activity while animals were subjected to passive movements or carried out active movements of individual body parts. These studies showed that neurons responding to leg movements are found in a dorsolateral zone of the putamen, neurons responding to orofacial movements are located ventromedially, and neurons responding to arm movement are found in a zone between the leg and orofacial areas.

Neurons in the putamen project to the caudoventral portions of both segments of the pallidum and to the lateral portions of the substantia nigra pars reticulata. In turn, the motor portions of the internal pallidal segment and the substantia nigra pars reticulata project to specific motor-related areas of the ventral lateral, ventral anterior, and centromedian nucleus of the thalamus. The motor circuit is then closed by projections from the ventral lateral and ventral anterior nuclei to the motor cortex, supplementary motor area, and premotor cortex. The centromedian nucleus, one of the intralaminar nuclei of the thalamus, projects largely to the putamen as part of a subcortical feedback loop.

The larger motor circuit consists of segregated subcircuits, each centered on an individual precentral motor field. These subcircuits are believed to be responsible for different aspects of motor processing, such as motor planning, coordination of sequences of movement, or movement execution. Evidence for the subcircuit organization comes from anatomical studies. Several stages of the basal ganglia circuitry in the same animal have been traced by Peter Strick and his colleagues using small intracerebral injections of herpes and rabies viruses. Taken up by neurons and transported transsynaptically, the virus particles can be stained in anatomical slices. Using this technique at different time points after the injection, one may visualize circuit elements that lie two or more synapses away from the injection site.

Figure 43–4 Four basal ganglia–thalamocortical circuits originate in four functionally distinct areas of frontal cortex. (ACA, anterior cingulate area; DLPFC, dorsolateral prefrontal cortex; FEF, frontal eye field; LOFC, lateral orbitofrontal cortex; M1, primary motor cortex; MOFC, medial orbitofrontal cortex; PM, premotor cortex; SEF, supplementary eye field; SMA, supplementary motor area.) (Adapted, with permission, from Alexander and Crutcher 1990.)

Separate injections of the primary motor cortex, supplementary motor area, and lateral premotor area produces retrograde labeling of separate populations of neurons in specific areas of the ventral lateral nucleus in the thalamus and separate populations of neurons in the internal pallidal segment, demonstrating that the separate cortical domains remain segregated throughout the basal ganglia networks. Segregated anterograde transsynaptic transport of input from cortical areas to the striatum and pallidum has likewise been shown, providing further support for the segregated circuit concept.

Because axons of cortical neurons terminate on a far smaller number of striatal neurons, there is considerable convergence of cortical information in the striatum. Similarly, the number of neurons in the pallidum and substantia nigra is smaller than that in the striatum, allowing further convergence along the direct and indirect pathways. However, given the somatotopic arrangement of striatopallidal and pallido-subthalamic projections, it appears that convergence occurs largely within rather than between the different basal gangliathalamocortical circuits and subcircuits.

The Motor Circuit Plays a Role in Multiple Aspects of Movement

The motor circuit has been examined in experimental studies in which portions of the basal ganglia were activated or inactivated, in studies using extracellular electrophysiological recordings of the activity of single neurons, as well as imaging and behavioral studies. Based on these investigations the motor circuit has been implicated in a wide range of motor behaviors including action selection, preparation for movement, movement execution, sequencing of movement, self-initiated or remembered movements, the control of movement parameters, and reinforcement learning.

The idea that the basal ganglia have a role in action selection and the initiation of movement was first suggested by early clinical observations in patients with movement disorders. The concept that the basal ganglia play a role in action selection, in the broadest sense, implies that they also participate in the acquisition of behaviors that lead to a reward or reinforcement and the avoidance of acts that lead to punishment or adverse outcomes. Reward may be simply the delivery of a pleasurable stimulus such as food, but may also involve the successful reaching of a goal or intended action. By modulating the strength of specific corticostriatal synapses, dopamine is widely implicated in this action selection function, as described below.

The general concept that the basal ganglia play a role in the acquisition and selection of beneficial behaviors later evolved into the idea that the basal ganglia act to focus specific movements through interactions between the direct (permissive) and indirect (inhibitory) pathways at the level of the internal pallidal segment, somewhat equivalent to the center-surround inhibition in a sensory system. This "focusing model" stems from the observation that the basal ganglia provide sustained inhibitory output to thalamocortical neurons. According to the model, cortical phasic activation of striatal neurons that contribute to the direct pathway transiently suppresses the high spontaneous discharge rate of movement-related neurons in the output nuclei of the basal ganglia. This in turn removes inhibition from specific thalamocortical neurons and allows cortical areas to become active, thus facilitating the selected movement. In contrast, phasic activation of striatal neurons that contribute to the indirect pathway, or of cortical neurons that project to the subthalamic nucleus, transiently increases inhibition of thalamocortical neurons and thereby inhibits movement. If the direct pathway is activated in anticipation of intended movements,

and the indirect pathway is activated simultaneously to broadly inhibit pallidal inhibitory output, the combination facilitates intended movements and suppresses competing ones.

Although this focusing model is attractive, there are several strong arguments against it. For instance, the hypothesis would require that axons in the indirect and hyperdirect pathways diffusely target large areas of the pallidum in order to prevent unwanted movements, whereas the direct pathway would act on small areas of the internal pallidal segment to selectively facilitate the selected movement. Neither of these anatomical prerequisites is supported by anatomic studies, which indicate instead that inputs of the indirect pathway to the internal pallidal segment from the subthalamic nucleus are highly topographic. Furthermore, pallidal activation during movement initiation is generally considered to occur too late to play a significant role in the selection of movement.

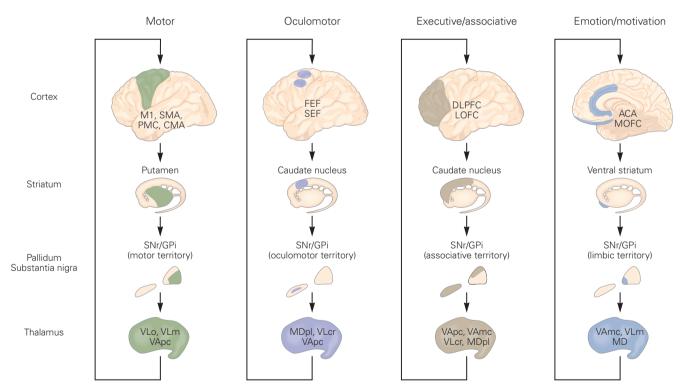

Figure 43–5 Global anatomy of cortico–basal ganglia—thalamocortical circuits. (Adapted, with permission, from Wichmann and DeLong 2006.)

Evidence that the motor circuit has a role in the preparation of movement comes from single-neuron recordings in monkeys performing delayed-response motor tasks. The animals were required to move an arm to a specified target after a delay period. In such studies the firing frequency of neurons in frontal and prefrontal cortical areas changed after animals were presented with a visual cue that specified the desired direction of movement (see Chapter 38). Changes similar to those found in the cortex are also found in the motor portions of the putamen, the internal segment of the globus pallidus, and the substantia nigra pars reticulata. These changes in activity occur while the animal is preparing the movement but not during the execution of the movement itself. Such changes are interpreted as involvement in a preparatory stage of motor control referred to as *motor set*.

Other basal ganglia neurons change their firing frequency phasically in relation to the onset of a movement, suggesting that they may be concerned with movement execution. As mentioned above, these changes in neural activity in a variety of stimulus-triggered movement tasks occur well *after* movement-related activities in the cerebral cortex or cerebellum, indicating that the basal ganglia do not participate in the initiation of such movements. This conclusion is reinforced by the results of a study with primates trained on a simple reaction time task: Pallidal lesions involving the motor circuit did not alter the reaction time between a cue and the movement triggered by that cue.

Changes in the activity of movement-related neurons in the internal pallidal segment correlate with the amplitude and velocity of arm movement, suggesting a role in the scaling of movement. In monkeys the activity of 30% to 50% of all movement-related neurons in the supplementary motor area, motor cortex, putamen, and pallidum is correlated with the direction of limb movement, but not with the activity of individual muscles. This suggests a role in the higher-level aspects of movement. The finding that individual neurons in the basal ganglia tend to be concerned with either the preparation or the execution of motor action suggests that these functions are mediated by separate subcircuits in the motor circuit.

Positron emission tomography and functional magnetic resonance imaging of humans have demonstrated that during simple finger or arm movements the peak activation of the basal ganglia occurs in the post-commissural putamen, and that changes in fundamental kinematic parameters, such as movement velocity, correlates with activity in the posteroventral pallidum, an area that has been identified as part of the motor territory of the basal ganglia in nonhuman primates

(Figure 43–6). By contrast, in cognitively demanding tasks—for example, tasks that require subjects to generate novel sequences of movement or to imagine hand movements—anterior portions of the striatum (caudate nucleus and putamen rostral to the anterior commissure) are activated, along with the prefrontal cortex and the anterior cingulate area.

Dopamine has opposite actions in the direct and indirect pathways. Direct-pathway neurons are facilitated by dopamine through the activation of dopamine D_1 receptors, whereas indirect-pathway neurons are inhibited by dopamine, possibly by means of the activation of dopamine D_2 receptors. By virtue of the different polarities of connections between the basal ganglia nuclei, dopamine release in the striatum reduces activity in the output nuclei, thereby leading to disinhibition of thalamocortical neurons and perhaps facilitation of movement. These effects of dopamine have significant implications for our understanding of the pathophysiology of movement disorders.

Mechanistic models of motor circuit function are attractive because of their relative simplicity, because they provide researchers with testable hypotheses, and because they may help us understand how disorders of dopaminergic input in the striatum affect motor performance. However, these models are largely speculative; there is little direct experimental support for an important role of the basal ganglia in the online-control of movements. As noted, lesions of the motor circuit in the internal pallidal segment have little or no effect on reaction time or movement time.

Dopaminergic and Cholinergic Inputs to the Striatum Are Implicated in Reinforcement Motor Learning

Given the potential function of dopamine in regulating the balance between direct and indirect pathways, it is perhaps surprising that dopaminergic neurons in the substantia nigra pars compacta that project to the striatum are not activated in relation to specific aspects of movement. Instead, many of these neurons are activated in connection with behavioral reinforcement cues (Figure 43–7). This finding has resulted in the development of a highly specific hypothesis regarding the role of dopaminergic neurons in reinforcement learning.

The specific interpretation is that changes in the activity of the dopaminergic cells during behavioral tasks signal a discrepancy, the reward prediction error, between the expectation of a reward and its delivery. This signal triggers the release of dopamine that helps to shape the animal's behavior by strengthening synapses that are involved in generating the rewarded

Movement-related activity

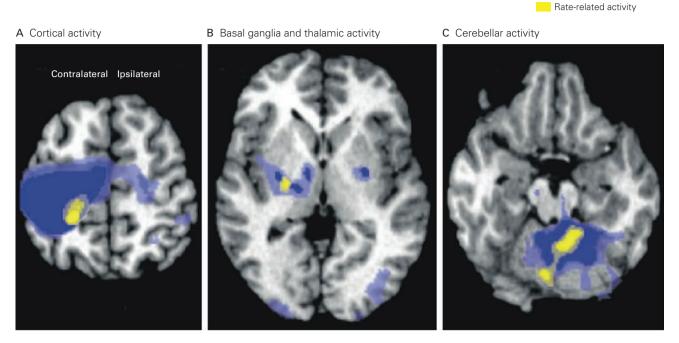

Figure 43–6 Areas of the brain with movement-related activity. PET images show significant levels of activity in human volunteers performing a sinusoidal arm movement. The images are shown superimposed on corresponding structural MRI images. The "ipsilateral" and "contralateral" hemispheres are in relation to the moving arm. (Adapted, with permission, from Turner et al. 1998.)

A. Movement-related activity in the cortex covers large portions of the primary sensorimotor, dorsolateral and mesial premotor, and dorsal parietal cortices, predominately contralateral to the moving extremity. Activity related to the rate of movement is

restricted to a small band of cortex surrounding the contralateral central sulcus.

B. Movement-related activity in the basal ganglia and thalamus is seen in motor-related portions of the basal ganglia and thalamus primarily on the side contralateral to the moving arm. Raterelated activity is restricted to the posterior globus pallidus.

C. A large portion of the anterior cerebellum ipsilateral to the moving arm is active during movement. Movement-related activity is seen in a band covering the mesial portions of the cerebellum.

behavior. To effectively fulfill this role, dopaminergic neurons signal the presence of reinforcing or salient cues with very short latency. The sources of this information have not been identified, but they may include subcortical areas such as the superior colliculus, the pedunculopontine nucleus, the raphe nuclei, the lateral habenular nucleus, the amygdala, or limbic areas of cortex.

In addition to dopaminergic neurons in the substantia nigra pars compacta, cholinergic interneurons in the striatum are also activated in rewarded behavioral tasks. These cells are highly interconnected and tonically active. Their discharge is briefly reduced in response to rewards, reinforcements, noxious stimuli, and other behaviorally salient stimuli. Such responses are shaped in part by input to these neurons from the centromedian nucleus of the thalamus. Recent studies

of the timing of cholinergic and dopaminergic inputs to the striatum suggest that the cholinergic interneurons may inform the medium spiny neurons in the striatum about the occurrence of salient stimuli (irrespective of their function as rewards), whereas the dopaminergic inputs may provide information about the behavioral value of the stimuli.

Chronic extracellular recordings have demonstrated that the striatal projection neurons alter their activity in the process of learning. Because the activity of striatal medium-sized spiny neurons is almost entirely driven by their excitatory cortical and thalamic inputs, such changes may reflect changes in these inputs to the striatum or in the strength of cortico- or thalamostriatal synapses through modification of the efficacy of synaptic transmission in the form of long-term potentiation (LTP), long-term depression

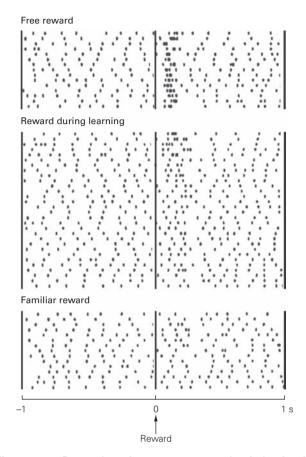

Figure 43–7 Dopaminergic neurons respond to behavioral rewards or reinforcements. Raster plots show the discharge of a dopaminergic neuron in a monkey. All trials are aligned to the time of presentation of a reward. The neuron responds each time a reward is given at random times (top). The responses to rewards decrease during learning of the association between a novel stimulus and a reward (middle). Once the reward has become familiar and predictable (lower), the neuron no longer responds to it. (Adapted, with permission, from Hollerman and Schultz 1998.)

(LTD), or spike-time dependent modulation of synaptic strength, brought about by the joint actions of the dopaminergic and cholinergic inputs. The striatum seems to be specifically involved with motor learning and the formation of habitual movement patterns (procedural memory). Storing such motor patterns in the form of larger behavioral units may be computationally advantageous to the brain—programmed sequences avoid the cost of repeatedly having to sequence individual movements.

The formation and execution of habitual movements appear to involve different areas of the striatum. During early stages of procedural learning the ventral

striatum and caudate nucleus seem to be the primary sites of activity, whereas during later stages of learning and the execution of learned movements the dorso-lateral striatum is more active. For example, experimental inactivation of the caudate nucleus in primates disrupts the acquisition of sequences of movement, whereas inactivation of the putamen interferes with the performance of previously learned sequences. As discussed earlier, however, lesions of the output from the motor circuit do not appear to have a significant effect on the execution of learned motor sequences.

Studies in songbirds also provide evidence that the basal ganglia are involved in motor learning. In some bird species lesions of the anterior forebrain pathway, the equivalent of the basal ganglia–forebrain circuitry in mammals, abolish the bird's ability to learn species-specific songs during its critical period for learning. Lesioning after the critical period does not interfere with song production but does prevent adaptive changes that may shape the bird's song in different acoustic environments, and the learned song may deteriorate over time.

Other Basal Ganglia Circuits Are Involved in the Regulation of Eye Movements, Mood, Reward, and Executive Functions

Because the patterns of connectivity of nonmotor circuits in the basal ganglia resemble those for the motor circuit, the fundamental processing in these different circuits is believed to be similar. For example, the role of the basal ganglia in the control of eye movements mirrors their role within the skeletomotor system. The oculomotor circuit originates from the frontal eye field and supplementary eye field, and engages oculomotor regions in the posterior caudate nucleus and precommissural putamen, oculomotor neurons in the external segment of the globus pallidus, the subthalamic nucleus and substantia nigra pars reticulata, and the mediodorsal, ventral anterior, and ventrolateral nuclei of the thalamus. In addition to this reentrant pathway that links the basal ganglia with the cerebral cortex, the substantia nigra pars reticulata provides descending projections to the superior colliculus that may be involved in the initiation and facilitation of saccadic eye movements (see Chapter 39).

The function of the descending nigrotectal pathway has been studied in detail, starting with seminal studies by Okihide Hikosaka and Robert Wurtz in the early 1980s. The available evidence indicates that voluntary saccades are initiated within the frontal eye

fields of the cerebral cortex. Cortical neuronal discharge activates the GABA-ergic medium spiny neurons in the oculomotor region of the caudate nucleus, which in turn inhibit the tonic activity of GABA-ergic neurons in the substantia nigra, via the direct pathway. The resulting pause in nigral activity results in a transient disinhibition of the neurons in the superior colliculus that drive the brain stem saccade-generating machinery, resulting in a saccade. The circuit may also have a role in cognitive events associated with movement, such as memory-guided saccades.

In a general sense the oculomotor circuit appears to function in a manner similar to that originally proposed for limb movements by the motor circuit. However, the effects of manipulation of the nigro-collicular pathway have no clear parallel in the motor circuit. Whereas inactivation of the substantia nigra results in a disruption of saccades and the emergence of irrepressible involuntary saccades, inactivation of the basal ganglia output site of the motor circuit does not result in excessive limb movements.

Two prefrontal circuits involved in different aspects of cognitive and executive function have been identified. The larger prefrontal circuit is divided into the dorsolateral prefrontal and lateral orbitofrontal circuits. The dorsolateral prefrontal circuit originates in Brodmann's areas 9 and 10 of the cerebral cortex and projects to the head of the caudate nucleus, which in turn projects directly and indirectly to the dorsomedial portion of the internal pallidal segment and the rostral substantia nigra pars reticulata. Projections from these regions terminate in the ventral anterior and mediodorsal nuclei of the thalamus and in the dorsolateral area of prefrontal cortex. The dorsolateral prefrontal circuit has been implicated in executive functions such as organizing behavioral responses to complex problems and using verbal skills in problem solving.

The *lateral orbitofrontal circuit* arises in the lateral prefrontal cortex and projects to the ventromedial caudate nucleus. It engages portions of the basal ganglia output structures and thalamus and then returns to the orbitofrontal cortex. It appears to play a major role in the mediation of empathic and socially appropriate behavior.

The *limbic circuit* begins with projections from the anterior cingulate and medial orbitofrontal cortices to the ventral striatum, which also receives input from the hippocampus, amygdala, and entorhinal cortices. The ventral striatum projects to the ventral and rostromedial pallidum and rostrodorsal substantia nigra pars reticulata. From there the pathway continues to neurons in the paramedian portion of the mediodorsal nucleus of the thalamus, which projects back to

the anterior cingulate cortex. The anterior cingulate circuit plays an important role in motivated behavior. Through inputs to the ventral tegmental areas and substantia nigra pars compacta, it may reinforce stimuli to diffuse areas of the basal ganglia and cerebral cortex.

Diseases of the Basal Ganglia Are Associated with Disturbances of Movement, Executive Function, Behavior, and Mood

Abnormalities in the Basal Ganglia Motor Circuit Result in a Wide Spectrum of Movement Disorders

Movement disorders arise from dysfunction of the basal ganglia–thalamocortical motor circuit, ranging from hypokinetic disorders, of which Parkinson disease is the best-known example, to hyperkinetic disorders, exemplified by Huntington disease, dystonia, and hemiballism.

Pathological changes in specific regions of the basal ganglia strongly affect neuronal activity throughout the entire basal ganglia—thalamocortical network and the activity of descending projections to the brain stem. The most severe and disruptive movement disturbances result from dysfunction in the striatum and subthalamic nucleus. By contrast, interruption of the major output nucleus of the basal ganglia, the internal segment of the globus pallidus, has little or no effect on movement. The reasons for these different effects are not understood. It seems, however, that the clinical features of specific disorders depend on unique combinations of changes in discharge rates and patterns, synchronization of discharge, and varying degrees of involvement of individual motor subcircuits.

Hypokinetic disorders are characterized by impairments of movement initiation (akinesia), reduction in the amplitude and velocity of voluntary movements (bradykinesia), muscular rigidity (increased resistance to passive displacements), and a 4–6 Hz tremor at rest and flexed posture. Hyperkinetic disorders, in contrast, are characterized by involuntary movements, such as chorea (random fragmented movements of individual body parts), ballism (large-amplitude movements particularly of the proximal limbs), and dystonia (slower, twisting movements and sustained abnormal postures).

A Deficiency of Dopamine in the Basal Ganglia Leads to Parkinsonism

Parkinson disease, first described by James Parkinson in 1817, affects over one million people in North America

alone. In addition to the cardinal features of this condition—akinesia, bradykinesia, muscular rigidity, and tremor—other prominent motor features include a shuffling gait, flexed posture, reduced facial expression, decreased blinking, and small handwriting. These motor features are summarily referred to as parkinsonism.

Another clinical aspect of Parkinson disease is a loss of the automaticity of movement and the need for increased voluntary control manifested as difficulty carrying out simultaneous movements. The disruption of automatic and well-learned movements is believed to reflect a loss of the basal ganglia's role in procedural learning.

The salient pathological feature of idiopathic Parkinson disease is degeneration of the dopaminergic cells in the substantia nigra pars compacta that project to the striatum and to a lesser extent to other basal ganglia nuclei. Dopamine loss in these areas is considered to cause most of the movement abnormalities in this disorder, since they respond to dopamine replacement therapies. Nonmotor features of the disease include depression and anxiety, cognitive impairment, sleep disturbances, and autonomic dysfunction. These nonmotor signs and symptoms respond poorly or not at all to dopamine replacement therapy.

According to recent studies these features may be caused by additional pathological changes that affect widespread areas of the brain, with a slowly progressive ascending involvement of the lower brain stem nuclei, including the dorsal motor nucleus of the vagus nerve, locus ceruleus, nucleus gigantocellularis, raphe nuclei, amygdala, and thalamus, as well as portions of the cerebral cortex. Because little is known about the specific physiologic changes produced by these nonmotor signs, we focus here on the better-known causes and effects of dopaminergic cell loss in Parkinson disease.

The etiology of Parkinson disease is uncertain in most patients, who are said to suffer from "sporadic" Parkinson disease. Nevertheless, the disorder is believed to result from a combination of environmental and genetic factors. Exposure to environmental toxins, such as pesticides, is thought to underlie the association of Parkinson disease with rural living and consumption of well water. Several such compounds are mitochondrial toxins that may damage dopaminergic cells by interfering with their energy metabolism. Other environmental factors, such as a history of smoking or caffeine consumption, are known to *lower* the risk of developing Parkinson disease.

Single-gene mutations may also result in parkinsonism. For example, in several families with autosomal dominant parkinsonism the disorder is linked to a defect in the gene on chromosome 4 encoding α-synuclein or to duplication or triplication of the gene. This protein is one of the major components of eosinophilic inclusions (Lewy bodies) that are found in degenerating neurons in the substantia nigra pars compacta. In both sporadic and hereditary forms of Parkinson disease the accumulation of α-synuclein appears to be a major factor accounting for neuronal dysfunction and cell death. More common than mutations in the α-synuclein gene are parkinsonismcausing defects in the parkin gene on chromosome 6, or the more recently identified LRRK2 gene mutation. The pathogenetic mechanisms triggered by these mutations are not clear. However, it appears that factors such as oxidative damage, dysfunction of cellular mechanisms involved in the removal of toxic metabolites, and abnormal cellular calcium handling may contribute to the loss of dopaminergic cells in parkinsonism.

Direct evidence for the reduction of dopaminergic inputs to the striatum comes from postmortem biochemical analyses and from PET studies in humans with Parkinson disease (Figure 43–8). With PET the dopaminergic system can be visualized in vivo. Such studies have demonstrated that the reduction of dopamine is most severe in the caudal putamen, the portion of the striatum containing the motor circuit. This result is consistent with the observation that the earliest and most prominent manifestations of the disease involve the development of motor signs and symptoms.

Postmortem studies that have compared the brains of parkinsonian and control patients, as well as studies in experimental animals, have shown that the first overt motor signs of the disease occur when 70% or more of striatal dopamine are lost, attesting to a significant capacity of the basal ganglia–thalamocortical network to compensate for changes in dopamine levels. The presymptomatic compensation for dopamine loss may occur within the dopaminergic system itself, through increased activity of healthy dopaminergic neurons, sprouting of remaining dopaminergic fibers, and changes in the synthesis, release, or metabolism or receptor sensitivity. Mechanisms independent of dopamine, such as synaptic changes in the thalamus or cortex, may also play a role.

Dopamine loss in other nuclei of the basal ganglia (specifically the subthalamic nucleus, the internal pallidal segment, and the substantia nigra pars reticulata) may also contribute to the manifestations of Parkinson disease. Whether dopamine loss in regions outside the basal ganglia, such as the thalamus and frontal cortex, is a factor in the development of parkinsonism has not been examined in detail.

Figure 43–8 Loss of dopamine in the striatum in Parkinson disease. Positron emission tomography (PET) images of ¹⁸F-DOPA uptake in the striatum in a normal subject and in a twin of a Parkinson patient show the extent of dopamine

metabolism. In the twin, ¹⁸F-DOPA uptake in the putamen was reduced when the subject was asymptomatic and more severely reduced five years later when symptomatic. (Adapted, with permission, from Brooks 2000.)

In the early 1980s a group of drug addicts injected themselves with a synthetic opioid that was contaminated with the meperidine analog MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), a potent mitochondrial toxin. Soon after the exposure some of these individuals developed profound and irreversible parkinsonism. Investigations by William Langston and others revealed that MPTP is a potent neurotoxin able to destroy selectively the dopaminergic neurons in the midbrain. An important consequence of this discovery was that it allowed researchers to develop a phenotypically and anatomically convincing animal model of dopamine depletion, the MPTP-treated primate. Anatomical and electrophysiological studies in these animals have contributed greatly to circuit models of the pathophysiology of Parkinson disease.

Early microelectrode recordings and neuroimaging studies in MPTP-treated primates demonstrated that induction of parkinsonism is accompanied by a decrease in the discharge rates of neurons in the external pallidal segment and an increase in activity the subthalamic nucleus and internal pallidal segment. These changes, along with the motor signs of parkinsonism, can be reversed by systemic administration of dopamine receptor agonists. These findings led to the development of a highly influential pathophysiologic model in which loss of dopaminergic input to the striatum led to increased activity in the indirect pathway and decreased activity in the direct pathway. Both of these changes are thought to lead to a net increase of the activity of neurons in the internal segment of the globus pallidus and the substantia nigra pars reticulata. This increase in basal ganglia output would result in increased inhibition of thalamocortical and midbrain tegmental neurons and account for the hypokinetic features of the disease.

This so-called "rate model" of Parkinson disease has now been largely supplanted by models that place greater emphasis on changes in neuronal firing pattern and synchrony. The rate model cannot account for the lack of akinesia following thalamic lesions and of involuntary movements following lesions of the internal pallidum, as demonstrated in both experimental animal models and surgically treated patients.

Electrophysiological recordings from the basal ganglia in parkinsonian animals and in humans undergoing neurosurgical procedures have shown obvious abnormalities of firing patterns (Figure 43–9). Abnormal burst discharges and synchronized oscillatory neuronal activity throughout the basal ganglia—thalamocortical circuitry are now thought to be at least as important for the development of parkinsonian akinesia and tremor as the changes in discharge rates. It is important to emphasize that the abnormalities that

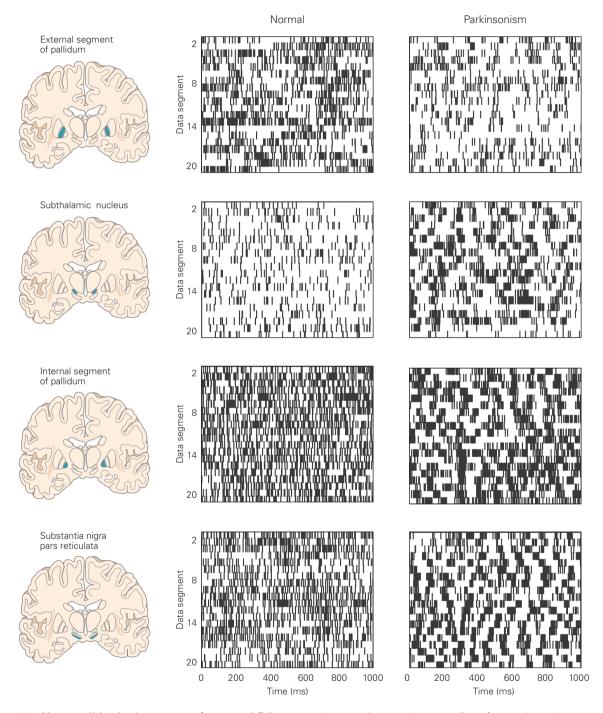

Figure 43–9 Abnormalities in the pattern of neuronal firing in the basal ganglia of parkinsonian monkeys. Raster plots

show continuous data recordings from selected representative neurons situated in the structures portrayed at the left.

result in parkinsonism in the earlier rate model as well as in the newer models that emphasize pattern abnormalities are primarily found in the indirect pathway of the basal ganglia.

Recording of cells in vitro and related neural network modeling studies have elucidated some of the mechanisms that may underlie these abnormal patterns of activity in the basal ganglia. Because most pathways in the basal ganglia are GABAergic, the role of rebound bursting, triggered by prolonged and pathological GABAergic inhibition of basal ganglia cells, has been extensively studied. One of the connections studied in detail is the interaction between the external segment of the globus pallidus and the subthalamic nucleus. Subthalamic nucleus neurons fire spontaneously as a result of the interplay between a persistent depolarizing Na⁺ current and after hyperpolarization, both of which follow each action potential and are in part caused by a K⁺ current that is activated by Ca²⁺ entry into the cell associated with the action potential. These normal oscillations are reset by single inhibitory postsynaptic potentials evoked by pallidal inputs. In the presence of stronger inhibition, as may occur when the synchronicity of pallidal activity is increased in parkinsonism, the hyperpolarization may be sufficient to trigger rebound depolarization, a phenomenon that appears to be central to the generation of bursts of action potentials in subthalamic nucleus neurons.

In recent years oscillatory activity in the basal ganglia has also been assessed by recording of local field potentials. Such recordings, reflecting the activity of larger ensembles of neurons and their synaptic inputs, can be made in parkinsonian patients implanted with macroelectrodes. It was found that parkinsonism is associated with high-amplitude oscillation in the high alpha and beta frequencies (10-30 Hz) in the subthalamic nucleus, internal pallidal segment, and cerebral cortex. Such oscillation may prevent the circuitry (specifically in the cortex) from engaging in oscillations at higher (gamma-band) frequencies. Gamma-band oscillatory activity in frontal cortex and related areas is seen as a prerequisite for normal movement, and lack of gamma-band oscillations may contribute to akinesia and bradykinesia.

Changes in the cortical activity of parkinsonian patients that may result from disordered subcortical inputs have also been evaluated by functional imaging. The time resolution of such imaging is too low to show directly any changes in firing patterns. However, PET scans of patients performing a movement show decreases in synaptic activity in the anterior cingulate, supplementary motor area, and dorsolateral prefrontal cortex. In addition, brain areas that are not normally

activated are recruited when patients perform visuomotor tracking. These changes may be compensatory or they may be part of the motor problem, as normal function in the newly recruited areas may be disrupted.

Progress in understanding the pathophysiology of Parkinson disease, and the finding that lesioning of motor circuit structures in parkinsonian animals has strong antiparkinsonian effects, has contributed to the resurgence of neurosurgical procedures to treat patients with advanced Parkinson disease. Initially, surgical lesioning of basal ganglia and thalamic targets was used to interrupt abnormal activity in the motor circuit, but these (irreversible) procedures have now been largely replaced by chronic high-frequency deep brain stimulation. In this less invasive and reversible procedure a programmable pulse generator, similar to a cardiac pacemaker, is placed subcutaneously and connected to a stimulating electrode inserted into the subthalamic nucleus or internal segment of the globus pallidus. Although the mechanisms of action of deep brain stimulation remain controversial, it is likely that chronic high-frequency stimulation in patients with Parkinson disease acts primarily by replacing the irregular, abnormal basal ganglia output to the cortex with a more regular and better-tolerated pattern that may then allow the cerebral cortex to function more normally. Alternatively, chronic stimulation may disrupt the abnormal and disruptive beta-frequency oscillations.

Reduced and Abnormally Patterned Basal Ganglia Output Results in Hyperkinetic Disorders

Lesions of the basal ganglia or imbalances in their neurotransmitter systems may result in involuntary movements such as hemiballism, Huntington disease, dystonia, and drug-induced involuntary movements.

Hemiballism is a hyperkinetic disorder characterized by spontaneous involuntary movements of the contralateral proximal limbs. Hemiballism most often results from lesions restricted to the subthalamic nucleus, usually as the result of small strokes. Experimental lesioning of the subthalamic nucleus in monkeys shows that involuntary movements result only when the lesion is confined to the nucleus and 20% or more of the nucleus is damaged. Such experimental lesions significantly reduce the tonic discharge of neurons in the internal segment of the globus pallidus and decrease the phasic responses of these neurons to limb displacement.

The reduced inhibitory input from the internal segment may permit thalamocortical neurons to respond in an exaggerated or abnormal manner to cortical or other inputs. If the basal ganglia inhibit planned or ongoing movements under physiological conditions, loss of this function could conceivably result in excessive movements, particularly involuntary movements. However, the finding that lesions of the internal segment relieve rather than worsen ballism and other hyperkinetic disorders argues strongly that this view is too simplistic, and that not only global activity changes but also altered patterns and synchrony of neuronal discharge in the thalamus and cortex play a major role in the generation and manifestation of hyperkinetic disorders.

Huntington disease is a hereditary disorder that affects men and women equally at a frequency of 5 to 10 per 100,000 individuals. The onset of the disease occurs most often after the third decade of life. The disease is characterized by the gradual development of motor symptoms, including chorea and eye-movement abnormalities. Nonmotor disturbances such as depression, behavioral disturbances, and cognitive impairment are also very common. Death occurs as the result of medical complications of the underlying neurological disease, in most cases 15 to 20 years after onset.

Huntington disease results from a defect on chromosome 4, affecting the gene that codes for the protein huntingtin, and is inherited in an autosomal dominant fashion. The disease is a prime example of a disorder resulting from trinucleotide repeats in a small portion of a gene (see Chapter 44). Higher numbers of trinucleotide repeats are associated with an earlier onset of the disease (anticipation).

Because of the lack of suitable animal models of Huntington disease, the pathophysiologic changes that underlie the clinical signs and symptoms in this disease are not as well established as those in Parkinson disease. The available evidence suggests that neuronal degeneration early in the disease process occurs primarily in the striatum, affecting strongly those output neurons that give rise to the indirect pathway. This reduces inhibition of neurons in the external segment of the globus pallidus leading to excessive inhibition of subthalamic nucleus neurons and a subsequent reduction in basal ganglia output. The functional inactivation of the subthalamic nucleus could explain the appearance of involuntary movements, which are similar to those seen in cases of hemiballism.

In later stages of Huntington disease a rigid and akinetic phenotype develops in most cases, possibly as the result of additional loss of the striatal neurons that project to the internal segment of the globus pallidus and substantia nigra pars reticulata. The resulting removal of inhibition from neurons of the internal segment may convert the hyperkinetic movement

disorder into a hypokinetic problem with increasing rigidity and akinesia.

The gradual loss of brain stem and cortical neurons may also contribute to some aspects of the movement disorder. The profound behavioral, psychiatric, and cognitive problems seen in Huntington disease reflect the fact that nonmotor areas of the cortex and basal ganglia are involved in the pathology.

Dystonia is distinguished clinically from chorea and hemiballism by the presence of slower, twisting movements, often resulting in abnormal postures. Dystonic movements are triggered by voluntary movements. Typically, patients show co-contraction of agonist-antagonist muscle groups and an inability to restrict movements to a single body part (overflow).

Most of the pathological conditions that result in dystonia affect the functioning of the basal gangliathalamocortical network. Dystonia may result from genetic defects, focal lesions of the basal ganglia or other structures, or disorders of dopamine metabolism. Whereas most cases of dystonia in adults are focal and nonfamilial, dystonia starting in childhood (or in young adults) is often generalized and genetic in origin. These genetic forms of dystonia do not feature prominent neuronal degeneration. A common autosomal dominant form of generalized dystonia originates from a trinucleotide deletion on chromosome 9, leading to the formation of a mutant variant of a normal protein (torsinA). Another interesting form of dystonia is dopamine-responsive dystonia, resulting from mutations in genes involved in the production of tetrahydrobiopterin, an essential cofactor in the biosynthesis of dopamine and other biogenic amines (see Chapter 13). Similar to Parkinson disease, this disorder can be treated with dopamine replacement.

The exact role of the basal ganglia in dystonia remains poorly defined, at least in part because existing animal models of the disease do not fully replicate the phenotype. Some of the evidence regarding the role of the basal ganglia in dystonia comes from recordings in a small number of human patients undergoing neurosurgical procedures and from PET scans of dystonic patients. These studies have found that the average discharge rate in both segments of the globus pallidus is low. As in the other movement disorders, abnormally patterned or synchronized activity of the basal ganglia output neurons may play an important role in the pathophysiology of dystonia. In some cases dopaminergic dysfunction may also contribute to the development of dystonia. This view is supported by the findings that alterations in striatal dopamine transmission are seen in some forms of dystonia, that dystonia may occur in untreated Parkinson disease, and that dystonia can be

seen in some patients receiving dopamine receptorblocking drugs.

Dystonia has also been interpreted as a disorder of abnormal synaptic plasticity in the basal ganglia. A key finding supporting this view is that sensorimotor maps in the basal ganglia—thalamocortical circuits are less defined in patients with focal hand dystonia than in controls. Because focal hand dystonia is often seen in the hands of patients with writer's cramp or musician's dystonia, it is interpreted as the end product of pathological synaptic plasticity in subcortical or cortical regions. Evidence for disordered plasticity in the cortico—basal ganglia—thalamocortical circuits also comes from the finding that the beneficial effects of surgical treatments such as lesioning or chronic electrical stimulation of the globus pallidus require weeks or months to develop.

Abnormal Neuronal Activity in Nonmotor Circuits Is Associated with Several Neuropsychiatric Disorders

Disturbances of the nonmotor basal ganglia—thalamocortical circuits may contribute to the development of cognitive and behavioral problems accompanying movement disorders and to primary psychiatric disorders, such as obsessive-compulsive disorder, Tourette syndrome, and depression. Although processes outside the basal ganglia—thalamocortical loop systems may also contribute to the psychiatric disturbances, we concentrate here on the possible involvement of the basal ganglia circuitry.

The evidence for the functional relevance of the nonmotor areas comes mostly from clinical observations. In addition, animal studies employing microinjections of a GABA receptor antagonist, bicuculline, into motor, associative, and limbic portions of the external pallidal segment in primates have provided evidence for the notion that different neurobehavioral syndromes arise from dysfunction of different basal ganglia-thalamocortical circuits. Injections in the limbic part of the external segment of the globus pallidus induced stereotypic movements, whereas injections in the associative part induced hyperactivity. As predicted, abnormal movements were observed only when bicuculline was injected into the motor territory. These studies provide experimental support for the proposed behavioral domains in the basal ganglia and their role in abnormal motor and nonmotor behaviors.

Damage to the dorsolateral prefrontal cortex or subcortical portions of the prefrontal circuit results in a variety of abnormalities related to cognitive or executive functions, whereas damage to the lateral orbitofrontal circuit (for example, in stroke patients) is associated with lack of empathy, emotional lability, irritability, and failure to respond to social cues.

One of the best-studied psychiatric disorders arising from pathology in a nonmotor circuit is obsessivecompulsive disorder. The stereotypic behaviors (rigid behavioral patterns) and compulsions that are characteristic of this disorder have been interpreted as evidence for dysfunctional procedural learning. Functional imaging studies of patients with this disorder have demonstrated abnormalities in activity in the basal ganglia-thalamocortical limbic circuits that originate in portions of the orbitofrontal and anterior cingulate cortices. The most prominent changes are seen in the ventral striatum, specifically in the nucleus accumbens and ventromedial caudate nucleus, and in the midbrain. The beneficial outcome of neurosurgical treatments directed at the limbic circuitry, such as lesioning or stimulation of the anterior limb of the internal capsule and the ventral striatum, or lesions involving fibers emanating from orbitofrontal or anterior cingulate cortex, is evidence that the limbic circuit is involved in obsessive-compulsive disorder.

Tourette syndrome, in which obsessive-compulsive symptoms are associated with motor or vocal tics (brief involuntary movements or vocalizations), is also characterized by abnormalities in the limbic circuit. The fact that dopamine receptor-blocking drugs suppress tics implicates the basal ganglia in these disorders. Additional changes in brain activity occur in cortical areas associated with motor functions, particularly in the sensorimotor cortex and supplementary motor area. Chronic stimulation of the limbic and motor circuit at the pallidal and thalamic levels is now being explored as a treatment of severe, refractory Tourette syndrome.

An Overall View

It is now clear that the basal ganglia, together with the thalamus and cerebral cortex, participate in a family of neuronal networks that are involved not only in motor functions, but also in the higher-order aspects of behavior, linking emotion, reward, executive function, and mood, and that they may have specific relevance for adaptive shaping of behavior and action selection.

Basal ganglia disturbances are a factor in many major movement, behavioral, and psychiatric disorders that appear to result from dysfunction in specific basal ganglia—thalamocortical circuits. The existing models of basal ganglia function and dysfunction have stimulated research on the role of the basal ganglia in health and disease and contributed to the development of successful new treatments for these disorders.

Nevertheless, the present models are not fully satisfactory because they are too strongly based on disease considerations and the outcome of inactivation and disruptive manipulations that have remote effects, that do not necessarily reflect the actual functions of the basal ganglia, and that do not fully incorporate the adaptive properties of the circuits involved. Accordingly, future versions of functional models will need to take into account many of the more recent findings, including the close interactions of the basal ganglia with the brain stem and other structures and the role of abnormal neuronal activity patterns and synchrony in the pathophysiology of movement, cognitive, behavioral, and psychiatric disorders.

An Overall View

THE MAJOR DEGENERATIVE DISEASES of the nervous system—Alzheimer, Parkinson, and the triplet-repeat diseases (Huntington and the spinocerebellar ataxias)—afflict nearly 5 million people in the United States alone, and more than 25 million people throughout the world. Although this is a relatively small percentage of the population, these diseases bring a disproportionate amount of suffering and economic loss, not only to their victims but also to the families and friends of the afflicted.

Most of these disorders strike in mid-life or later; aging itself may in fact contribute to susceptibility. With the exception of Alzheimer disease, the first symptoms to appear usually involve loss of control of fine motor movements, although Huntington disease can first manifest itself in cognitive deficits. Nevertheless, the end result is the same. After a lengthy period of progressive deterioration, usually 10 to 20 years, the affected individual dies a terrible, helpless death.

The late-onset neurodegenerative diseases can be grouped conceptually into two categories: sporadic (unknown etiology) and inherited. Alzheimer disease and Parkinson disease are predominantly sporadic; inherited forms afflict a small number of patients. The triplet-repeat diseases, however, are notable for their dominant pattern of inheritance and the dynamic nature of the pathological mutation, an elongation of a CAG repeat tract that is subject to further expansion. Among the triplet-repeat neurodegenerative diseases are Huntington disease, the spinocerebellar ataxias, dentatorubropallidoluysian atrophy, and spinobulbar muscular atrophy. Identification of the molecular basis of some of these disorders has facilitated

diagnosis and classification and provides hope for eventual treatment.

Expanded Trinucleotide Repeats Characterize Several Neurodegenerative Diseases

Huntington Disease Involves Degeneration of the Striatum

Huntington disease usually strikes in early or middle adulthood and affects 5 to 10 people per 100,000. The clinical presentation includes loss of motor control, cognitive impairment, and affective disturbance. Motor-control problems most commonly manifest themselves early as chorea, involuntary jerky movement that involves the small joints at first but then gradually creates instability of gait as the trunk and legs are affected. Fast, fluid movements are replaced by rigidity and bradykinesia (difficulty initiating action and unusually slow movements).

Cognitive impairment—such as difficulty in planning and executing complex functions—typically appears along with the involuntary movements but may be detected by formal neuropsychological testing even prior to motor dysfunction. Affective disturbances (psychiatric and behavioral features) include depression, irritability, social withdrawal, and disordered sleep. Hypomania and increased energy occur in 10% of the patients, whereas frank psychosis with delusions occurs in a smaller subset.

In adult patients the disease progresses inexorably to death some 17 to 20 years after onset. Juvenileonset cases suffer a more rapid course of the disease and within only a few years typically develop bradykinesia, dystonia (spasm of the neck, shoulders, and trunk), rigidity (resistance to the passive motion of a limb), seizures, and severe dementia.

The pathological hallmark of Huntington disease is degeneration of the striatum, with the caudate nucleus being more affected than the putamen. Loss of a class of inhibitory interneurons in the striatum, the medium spiny neurons, reduces inhibition of neurons in the external pallidum (see Chapter 43). The resulting excessive activity of the pallidal neurons inhibits the subthalamic nucleus, which could account for the choreiform movements. As the disease progresses and striatal neurons projecting to the internal pallidum degenerate, rigidity replaces chorea. Abnormalities in corticostriatal projections are thought to contribute to pathogenesis. Juvenile cases suffer a more severe and generalized pathology that often includes cerebellar Purkinje cells.

Huntington disease is an autosomal dominant disorder and one of the first human diseases to have its gene mapped using polymorphic DNA markers. It is caused by expansion of a translated CAG repeat that encodes a glutamine tract in the huntingtin protein. Normal or wild-type alleles have 6 to 34 repeats, whereas disease-associated alleles typically have 36 or more repeats and are quite unstable when transmitted from one generation to the next, especially through paternal germ cells.

The dynamic nature of the mutation, expanding in successive generations, accounts for the greater severity of the disease in juvenile-onset cases, a phenomenon known as anticipation. The length of the repeat correlates inversely with the age of onset, one of the many common features of neurodegenerative diseases caused by CAG-repeat expansions (Figure 44–1). Huntington disease-like 2 (HDL2), a rare neurodegenerative disorder that is clinically similar to Huntington disease, is caused by CTG expansion in junctophilin 3.

Huntington disease appears to be a true dominant disease in that patients homozygous for the condition do not differ significantly from their heterozygous siblings. The expanded glutamine tract causes the huntingtin protein to gain toxic function in addition to its normal function. Huntingtin is expressed throughout the brain in the cytoplasm, where it associates with microtubules, with a minor fraction present in cell nuclei. Although its precise functions are unknown, huntingtin is an essential protein in normal embryonic

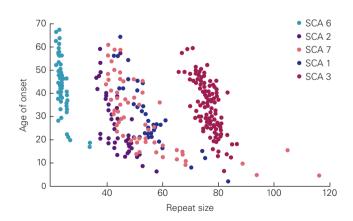

Figure 44–1 The length of the CAG repeat and age of onset in spinocerebellar ataxia are inversely correlated. The longer the CAG tract, the earlier the onset for a given disease. Specific repeat lengths, however, have different results depending on the host protein. For example, a 52-repeat of CAG causes juvenile onset of symptoms in spinocerebellar ataxia type 2 (SCA2), adult onset in spinocerebellar ataxia type 1 (SCA1), and no disease in spinocerebellar ataxia type 3 (SCA3).

development as shown by mouse knock-out studies; it is also essential for neuronal integrity in the postnatal brain.

Spinobulbar Muscular Atrophy Is Due to Abnormal Function of the Androgen Receptor

Spinobulbar muscular atrophy (Kennedy disease), the only X-linked disorder among the neurodegenerative diseases discussed in this chapter, is caused by expansion of a translated CAG repeat in the androgen receptor protein, a member of the steroid hormone receptor family. Only males manifest symptoms; the mutant androgen receptor is toxic when in the nucleus, and such localization requires the male hormone androgen. Proximal muscle weakness is usually the presenting symptom; eventually the distal and facial muscles weaken as well. Muscle wasting is prominent, secondary to degeneration of motor neurons.

Bulbar dysfunction results from loss of brain stem motor neurons. Many patients also develop gynecomastia, late hypogonadism, and sterility, indicating the loss of androgen receptor function. Individuals lacking androgen receptor function without expansion of CAG repeats do not, however, develop motor neuron degeneration. It thus appears that the glutamine expansion causes a partial loss of function that accounts for the secondary sexual characteristics and a partial gain of function that affects neurons and produces the neurological phenotype.

Hereditary Spinocerebellar Ataxias Include Several Diseases with Similar Symptoms but Distinct Etiologies

The spinocerebellar ataxias and dentatorubropallidoluysian atrophy are dominantly inherited neurodegenerative diseases that, for all their heterogeneity, are characterized predominantly by dysfunction of the cerebellum, spinal tracts, and various brain stem nuclei. The basal ganglia, cerebral cortex, and peripheral nervous system are also affected in some subtypes or in isolated cases (Table 44–1).

The two clinical features common to all the spinocerebellar ataxias are ataxia and dysarthria. These typically appear in mid-adulthood and gradually worsen, making walking impossible and speech incomprehensible. The brain stem dysfunction manifests itself through difficulties in swallowing and breathing and eventually causes death.

Features such as chorea or dementia are associated more strongly with one spinocerebellar ataxia than

others, but these symptoms are so variable that they cannot be reliably used to refine the diagnosis. Even individuals within the same family can present a quite different clinical picture. Thus, although the spinocerebellar ataxias are single-gene Mendelian disorders, individual genetic makeup and environmental influences clearly affect the clinical-pathological situation.

For example, Machado-Joseph disease and spinocerebellar ataxia type 3 (SCA3) had been regarded clinically as distinct diseases before it was discovered that they are caused by mutations in the same gene. The clinical confusion arose by historical accident. The most prominent features of the Portuguese families first studied by Machado and Joseph were bulging eyes, faciolingual fasciculations, parkinsonism, and dystonia, whereas the first SCA3 patients had features more reminiscent of SCA1 (hypermetric saccades and brisk reflexes in addition to the characteristic ataxia and dysarthria). We now know that these apparent clinical differences are at least partially attributable to differences in length of the CAG repeats. Nonetheless, differences in the activity of other proteins caused by genetic variations are probably also at play.

Although the age of onset within each type of ataxia depends on the number of CAG repeats in the gene (Figure 44–1), the toxicity of the abnormally long glutamine tract in the protein product depends on the protein: Expanded glutamine tracts have different effects in different proteins. For example, very short repeat lengths that are detrimental to Purkinje cells in SCA6 are nonpathogenic in other SCAs. In fact, the CAG expansion in SCA6 is the shortest of all the spinocerebellar ataxias: 21 to 33 repeats in mutants compared to fewer than 18 in normal alleles. In contrast, the gene responsible for SCA7 normally tolerates a few dozen CAG repeats, and in the disease state undergoes some of the largest expansions seen in any spinocerebellar ataxia (hundreds of CAGs). (Table 44–2.)

Besides tolerating different CAG repeat lengths, the gene products of mutated genes in polyglutamine diseases vary widely in function. The affected gene product in SCA1, ataxin-1, seems to be important for learning and memory; it is predominantly a nuclear protein that shuttles to the cytoplasm and can bind RNA in vitro, which suggests that it might play a role in RNA transport and processing. The affected gene product in SCA6, CACNA1A, is the α_{1A} subunit of the voltage-gated Ca²⁺ channel; interestingly enough, loss-of-function mutations in the gene (not caused by CAG repeats) have been reported in patients with episodic ataxia and familial hemiplegic migraine. In SCA17 the affected gene product is the TATA boxbinding protein, an essential transcription factor.

Table 44–1 Pattern of Inheritance and Main Clinical Features of Neurodegenerative Diseases Caused by Unstable Trinucleotide Repeats

Disease Inheritance		Typical presenting features	Principal regions affected	
SBMA	X-linked recessive	Muscle cramps, weakness, gynecomastia	Lower motor neurons and anterior horn cells	
Huntington	AD	Cognitive impairment, chorea, Striatum, cortex depression, irritability		
Huntington-like 2	AD	Cognitive impairment, chorea, Striatum, cortex depression, irritability		
SCA1	AD	Hypermetric saccades, ataxia, dysarthria, ophthalmoparesis	Purkinje cells, dentate nucleus, inferior olive	
SCA2	AD	Ataxia, hyporeflexia, slow saccades	Purkinje cells, granule cells, inferior olive	
SCA3	AD	Ataxia, gaze-evoked nystagmus, bulging eyes, dystonia, spasticity	Pontine neurons, substantia nigra, anterior horn cells	
SCA6	AD	Ataxia, late onset (>50 years of age)	Purkinje cells, granule cells	
SCA7	AD	Ataxia, visual loss due to retinal degeneration, hearing loss	Purkinje cells, retina (cone and rod degeneration)	
SCA8	AD	Scanning dysarthria, ataxia	Purkinje cells	
SCA10	AD	Ataxia and seizures	Purkinje cells	
SCA12	AD	Early arm tremor, hyperreflexia, ataxia	Purkinje cells (cortical and cerebellar atrophy)	
SCA17	AD	Dysphagia, intellectual deterioration, ataxia, absence seizures	Purkinje cells, granule layer, upper motor neurons	
DRPLA	AD	Dementia, ataxia, choreoathetosis Dentate nucleus, red nucleus, g pallidus, subthalamic nucleus, cerebellar cortex, cortex		

 $AD, autosomal\ dominant;\ DRPLA,\ dentatorubropallidoluysian\ atrophy;\ SBMA,\ spinobulbar\ muscular\ atrophy;\ SCA,\ spinocerebellar\ ataxia.$

The affected product in dentatorubropallidoluysian atrophy, atrophin-1, is thought to be a corepressor based on functional studies of its probable ortholog in *Drosophila*. Despite these differences, some pathogenetic mechanisms may be common to the polyglutamine diseases, as discussed later in this chapter.

A few spinocerebellar ataxias are caused by unstable trinucleotide repeats other than CAG (Table 44–2). Spinocerebellar ataxia type 8 is caused by an expansion of a CTG repeat in the 3' untranslated region of a transcribed RNA with no open reading frames. The mutation responsible for SCA12 is a CAG repeat, but it occurs in a noncoding region upstream of a brain-specific regulatory subunit of the protein phosphatase 2A. Spinocerebellar ataxia type 10 is unique in that it is caused by massive expansion of a pentanucleotide (ATTCT) repeat in the intron of a novel gene. The

pathogenic mechanisms accounting for the dominant phenotypes in spinocerebellar ataxia types 8, 10, and 12 are not yet known.

Parkinson Disease Is a Common Degenerative Disorder of the Elderly

Parkinson disease, one of the more common neurodegenerative disorders, affects 1% to 2% of the population older than 65 years of age. Patients with Parkinson disease suffer from a resting tremor, bradykinesia, rigidity, and impairment in their ability to initiate and sustain movements. Affected individuals walk with a distinctive shuffling gait, and their balance is often precarious. Spontaneous facial movements are greatly diminished, such that the face has a mask-like, expressionless appearance. The pathological hallmark of Parkinson disease is progressive loss of dopaminergic neurons, mainly in the substantia nigra (see Chapter 43).

Although the majority of parkinsonian cases are sporadic, studies of rare familial cases have provided insight into the genetic factors that predispose individuals to this disorder. Here we focus on how the genetic bases of some forms of Parkinson disease provides insights into sporadic Parkinson disease and link the pathogenic mechanism of parkinsonism to that seen in the polyglutamine disorders.

Both autosomal dominant and recessive inheritance patterns have been documented in familial parkinsonism. To date, several genetic loci have been mapped (designated PARK1–PARK8, PARK10, and PARK11), and the genes for all but three of these loci (PARK3, PARK10, and PARK11) have been identified (Table 44–3).

Parkinson disease type 1 (PARK1) is the locus for the dominantly inherited Parkinson disease caused by mutations in the gene α -synuclein. Two mutations in α -synuclein have been identified: A53T has been

described in several Greek families, whereas A30P has been identified in one German family. Mutations in α -synuclein have not been identified in sporadic Parkinson disease. However, because the α -synuclein protein is a primary component of the Lewy bodies in the substantia nigra of patients with sporadic disease as well as those with PARK1, α -synuclein mutations could play an important role in the pathogenesis of the sporadic disease.

The function of the α -synuclein protein is not yet known, but its abundance in presynaptic terminals suggests a role in presynaptic function and perhaps synaptic plasticity. Patients with α -synuclein mutations differ from those with sporadic Parkinson disease in that the age of onset is earlier (a mean of 45 years), and they exhibit fewer tremors and more rigidity, cognitive decline, myoclonus, central hypoventilation, orthostatic hypotension, and urinary incontinence.

Parkinson disease type 2 (PARK2) is an autosomal recessive disease characterized by early onset (as young as three years of age), dystonia, brisk deep-tendon

Table 44-2 Hereditary Ataxias Caused by Expansion of Unstable Trinucleotide Repeats

					Repeat lengths	
Disease	Gene	Locus	Protein	Mutation	Normal	Disease
SCA1	SCA1	6p23	Ataxin-1	CAG repeat in coding region	6-44*	36–121
SCA2	SCA2	12q24.1	Ataxin-2	CAG repeat in coding region	15–31	36-63
SCA3 (Machado- Joseph disease)	SCA3, MJD1	14q32.1	Ataxin-3	CAG repeat in coding region	12–40	55–84
SCA6	SCA6	19p13	α_{1A} subunit of voltage-gated Ca^{2+} channel	CAG repeat in coding region	4–18	21–33
SCA7	SCA7	3p12-13	Ataxin-7	CAG repeat in coding region	4–35	37–306
SCA8	SCA8	13q21	None	CTG repeat in the 3' terminal exon (antisense)	16–37	110–250
SCA10	SCA10	22q13ter	Ataxin-10	Pentanucleotide (ATTCT) repeat in the intron	10–20	500-4500
SCA12	SCA12	5q31-33	Protein phosphatase 2A	CAG repeat in 5' UTR	7–28	66–78
SCA17	TBP	6qter	TATA-binding protein	CAG repeat in coding region	29–42	47–55
DRPLA	DRPLA	12q	Atrophin-1	CAG repeat in coding region	6–35	49-88
FXTAS	FMR1	Xq27.3	FMRP	CGG repeat in 5' UTR	6-60	60-200

^{*}Alleles with 21 or more repeats are interrupted by 1–3 CAT units; disease alleles contain pure CAG tracts.DRPLA, dentatorubropallidoluysian atrophy; FXTAS, fragile X-associated tremor ataxia syndrome; SCA, spinocerebellar ataxia.

Table 44-3 Genetics and Main Clinical Features of Inherited Parkinson Disease

Disease	Locus map	Inheritance pattern	Protein	Main features
PARK1, PARK4	4q21	AD	α-synuclein	Early onset, rigidity, and cognitive impairment
PARK2	6q25.2-q27	AR	Parkin	Juvenile onset, dystonia
PARK3	2p13	AD	Unknown	Adult onset, dementia
PARK5	4p14	Probably AD	UCH-L1	Adult onset
PARK6	1p36	AR	PINK1	Early onset, dystonia
PARK7	1p36	AR	DJ-1	Early onset, behavioral disturbance, dystonia
PARK8	12q12	AD	LRRK2	Classic PD
PARK10	1p32	Unknown	Unknown	Classic PD
PARK11	2q36-q37	Unknown	Unknown	Classic PD

AD, autosomal dominant; AR, autosomal recessive; PARK, PD, Parkinson disease.

reflexes, and cerebellar signs in addition to the classic Parkinson disease phenotype. More than 60 different mutations have been identified in the gene PARK2, and most are clearly inactivating, demonstrating that this form of the disease is caused by loss of function of the gene product, parkin. Whereas α -synuclein mutations have not been detected in the sporadic disease, mutations in the parkin gene have been found in isolated cases of early-onset Parkinson disease and in one patient with onset at 65 years of age. Loss of dopaminergic neurons in the substantia nigra is typical of this form of the disease, but Lewy bodies are not as common as in sporadic or PARK1 cases.

The *parkin* gene encodes an E3 ubiquitin ligase of the RING-finger family that transfers activated ubiquitin to lysine residues in proteins destined for degradation by proteasomes. The ligase is quite specific and transfers ubiquitin to only a few substrates. Some substrates for parkin have been identified, including a putative transmembrane G protein-coupled receptor named parkin-associated endothelin receptor-like receptor (Pael-R), the synaptic vesicle protein CDCrel-1, the O-glycosylated form of α -synuclein, the α -synuclein interactor synphilin-1, and parkin itself.

A missense mutation, I93M, in the gene encoding ubiquitin C-terminal hydrolase-L1 (UCH-L1) has been identified in a family with an apparently autosomal dominant Parkinson disease, PARK5. UCH-L1 is an abundant protein in the brain and is thought to cleave polyubiquitin chains as the ubiquitinated proteins are being degraded by the proteasome. This activity

is decreased in individuals with the 193M mutant. A homologous protein is necessary for the formation of memory in the marine mollusk *Aplysia*.

Parkinson disease type 6 (PARK6) is caused by mutations in a gene that encodes a PTEN-induced putative kinase 1 (PINK1), a mitochondrial protein kinase, whereas Parkinson disease type 7 (PARK7) is caused by mutations in a gene that encodes DJ-1, a protein that may function as a sensor of oxidative stress. Mutations in the gene encoding the leucine-rich repeat kinase 2 (LRRK2) cause Parkinson disease type 8 (PARK8) as well as a small percentage of sporadic Parkinson disease cases.

Selective Neuronal Loss Occurs After Damage to Ubiquitously Expressed Genes

A perplexing aspect of these neurodegenerative diseases is that the altered gene products are widely and abundantly expressed not only in the nervous system but also in other tissues, yet the phenotypes are predominantly neurological. Moreover, the phenotypes reflect dysfunction in only specific groups of neurons (Figure 44–2), a phenomenon referred to as neuronal selectivity.

Why are striatal neurons the most vulnerable in Huntington disease, whereas the Purkinje cells are targeted in the spinocerebellar ataxias (SCA)? Why are the dopaminergic neurons in the substantia nigra primarily affected in Parkinson disease even though α -synuclein, parkin, DJ-1, PINK1, LRRK2, and UCH-L1 are abundant in many other neuronal groups? Although definitive answers are not yet available, there are some clues.

In the polyglutamine diseases the selectivity of the cellular pathology diminishes as the length of the glutamine tract increases: the more severe the mutation, the greater the number of neuronal groups affected. This is especially evident in the early-onset forms characterized by extremely long repeats. Juvenile SCA1 patients suffer from dystonia, rigidity, and cognitive impairment, features that overlap with Huntington disease and dentatorubropallidoluysian atrophy.

Juvenile SCA7 patients can suffer seizures, delusions, and auditory hallucinations, and infantile cases also develop somatic features, including short stature and congestive heart failure. Spinocerebellar ataxia type 7 also causes progressive blindness owing to dystrophy of both rods and cones; interestingly, cases of infants with SCA2 who also suffer retinal degeneration have recently been reported.

These and similar observations suggest that various cell types have different thresholds of vulnerability to toxic proteins with expanded glutamine tracts. Retinal cells, for example, seem more resistant to polyglutamine toxicity than cerebellar neurons, but more

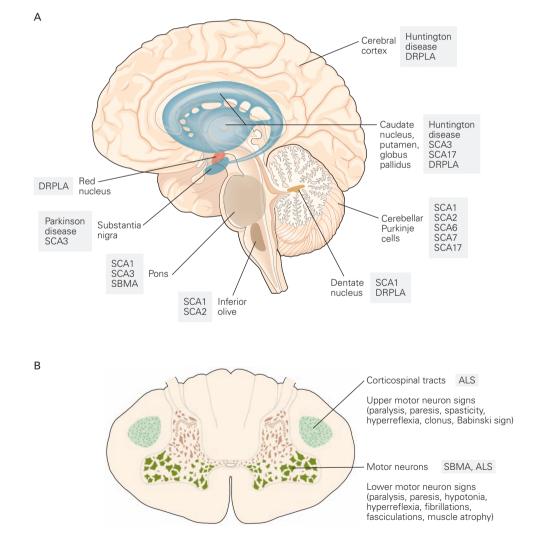

Figure 44–2 Primary sites of neuronal degeneration in the trinucleotide repeat diseases and Parkinson disease.

A. Brain regions most typically affected by adult-onset disease (see Table 44–1).

B. Comparison of neuropathology of amyotrophic lateral sclerosis (ALS) and spinobulbar muscular atrophy (SBMA).

vulnerable than cardiac myocytes. Once the number of glutamines in the tract expands beyond a certain length—which varies from one protein to the next—no cell is safe.

Studies using mouse models suggest that protein misfolding is responsible for polyglutamine disorders. The longer the glutamine tract, the more severe the misfolding and protein accumulation. As the tracts become very long, even cells with lower concentrations of disordered gene product become vulnerable. Indeed, studies of animal models show that even a doubling in concentration can be the difference between phenotypic manifestation and apparent normality. It is therefore conceivable that the neurons affected in each disease have more mutant protein than do the less vulnerable neurons. Although not detectable by current immunolabeling techniques, this increment would nevertheless be sufficient to interfere with cellular function if the neuron was exposed to the toxic mutant protein over decades.

Other major contributors to selective vulnerability might be variations in the levels of proteins that interact with or help dispose of the mutant proteins. Variations in the genes encoding such proteins could contribute to the clinical variability that is so prominent among ataxia families.

Why are neurons affected before other cells? As the organism ages, slight insults that have small detrimental effects could be exacerbated by the extra challenge the mutant protein presents to the protein-folding machinery. Because neurons are post-mitotic, they might be especially sensitive to perturbations in the balance of intracellular factors. If the organism could survive the neurological assault long enough, other tissues might also eventually show signs of distress.

Animal Models Are Powerful Tools for Studying Neurodegenerative Diseases

Animal models have proven extremely valuable for probing the pathogenesis of various neurodegenerative diseases and investigating therapies. Because of the ease in making mutations, the mouse has been the favored animal for modeling neurological disorders, but *Drosophila* models also have proven useful in the delineation of genetic pathways.

Mouse Models Reproduce Many Features of Neurodegenerative Diseases

With the exception of PARK2, the neurodegenerative diseases discussed here are caused mostly by a gain of function rather than loss of function. Thus most of the

genetically engineered mice that model these diseases are created using two techniques. In transgene experiments an allele harboring the mutant gene is overexpressed, whereas in knock-in experiments a human mutation, such as an expanded CAG tract, is inserted into an endogenous mouse locus to control expression of the gene product temporally and spatially (see Box 3-2). In some mutants, such as spinocerebellar ataxia types 1, 2, 3, and 7, dentatorubropallidoluysian atrophy, and some Huntington disease models, a fulllength cDNA with either wild-type or expanded alleles is overexpressed either in a particular class of neurons or in a larger population of cells. In other mutants, such as SCA3, Huntington disease, and spinobulbar muscular atrophy, truncated versions of the coding regions are expressed.

Knock-in mice have been generated for Huntington disease and spinocerebellar ataxia types 1 and 7. These models confirm that features other than the length of the expanded glutamine tract affect the toxicity of the tract. As noted above, the same expansion in two different host proteins affects cells differently. For example, in human patients 37 repeats cause SCA2 but not SCA3 (see Figure 44–1 and Table 44–2). In mouse models, however, the relationship of the length of the tract to the rest of a given host protein is a good predictor of toxicity.

Severe, widespread, nonselective neuronal dysfunction occurs in both transgenic mice in which the glutamine tract constitutes a major portion of the protein and mice bearing a truncated protein with a relatively large glutamine tract. In contrast, mice that express full-length proteins containing a CAG repeat develop a neurological syndrome that progresses more slowly. Similarly, weakly expressing promoters generally produce more selective neuronal dysfunction (Figure 44-3). In some cases expression of the full-length protein with even a moderately large expansion does not cause neurological dysfunction, but a truncated version bearing a similar repeat size produces the disease phenotype. In sum, a glutamine tract of a certain length is more toxic when in isolation or flanked by short peptide sequences, that is, when it occupies a larger proportion of the protein.

In knock-in mice with 80 to 111 glutamine repeats, neurological dysfunction is barely detectable; only when the repeat length is expanded to approximately 150 glutamines does a neurological phenotype become apparent. Because polyglutamine toxicity takes time to exert its effects, longer repeats are necessary to see a phenotype during the short life span of a mouse. However, massive overproduction of the mutant protein, as in transgenic mice, can compensate for a moderate

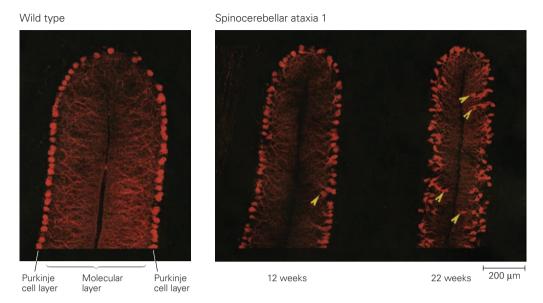

Figure 44–3 Progressive Purkinje cell pathology in a mouse model of spinocerebellar ataxia type 1. Cerebellar sections from a wild-type mouse and mice expressing a spinocerebellar ataxia type 1 (SCA1) transgene with 82 glutamines in Purkinje cells at 12 and 22 weeks of age. Calbindin immunofluorescence

staining marks the Purkinje cells and their extensive dendritic arbors. In spinocerebellar ataxia type 1 there is progressive loss of dendrites, thinning of the molecular layer, and Purkinje cell displacement (yellow arrowheads). (Images, used with permission, by H.T. Orr.)

repeat length and brevity of exposure to the toxic repeat. Indeed, overproduction of wild-type ataxin 1 or α -synuclein in mice results in mild neurological dysfunction.

Analysis of brain tissue from patients and experimental mice reveals that misfolded proteins tend to accumulate in various neurons, sometimes forming visible aggregates (Figure 44–4). Lewy bodies and abnormal accumulation of α -synuclein, as observed for years in patients, develop in mouse models of Parkinson disease. Although protein accumulation is common to all these neurodegenerative disorders in humans and their respective mouse models, the localization of the accumulated protein in the cell varies, and location within the cell is a factor in the protein's pathogenicity. For example, mutant ataxin 1 that remains in the cytoplasm because of a mutant nuclear-localization signal exerts no detectable toxic effects.

The fact that mutated proteins accumulate in mouse models that do not overproduce the proteins as well as in human patients who carry a single mutant allele suggests that neurons have difficulty clearing the proteins. Support for this hypothesis comes from the finding that ubiquitin and proteasome components, the machinery of protein degradation, localize to the site of protein aggregates in both human and mouse tissues.

Invertebrate Models Manifest Progressive Neurodegeneration

Several invertebrate models have been used to study polyglutamine proteins and α -synuclein. The similarities in the pathogenic effects of these proteins across species are remarkable.

Flies with high levels of human α -synuclein develop age-dependent, progressive degeneration of dopaminergic neurons and have α -synuclein-immunoreactive cytoplasmic aggregates reminiscent of Lewy bodies. As in the mouse model, high levels of either wild-type or mutant α -synuclein in flies induce this phenotype, and the toxic effect of the expanded glutamine tract is reduced as more amino- or carboxylterminal amino acids are added to the polypeptide. Overproduction of wild-type or mutant ataxin-1 in flies induces progressive neuronal degeneration that is dependent on protein levels but is more severe for the mutant when protein levels are similar.

Polyglutamine toxicity has also been evaluated in the nematode *Caenorhabditis elegans* by expressing an amino terminal fragment of huntingtin containing glutamine tracts of different length. Neuronal dysfunction and cell death occur in worms expressing expanded alleles.

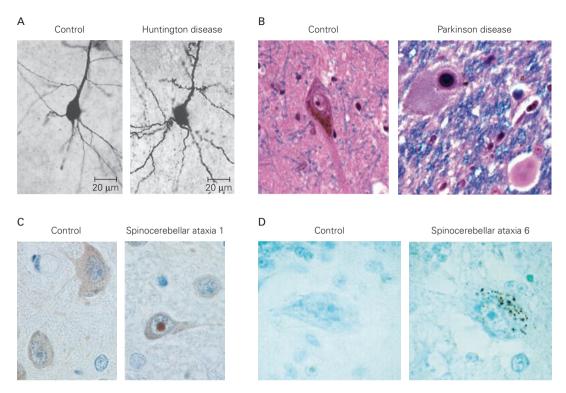

Figure 44–4 Neuropathological features of selected neuro-degenerative disorders. (Control images in A, B, C, and D are used, with permission, from J-P Vonsattel. Huntington image (A), used with permission, from M. Di Figlia and J-P. Vonsattel. SCA1 image (C), used with permission, from H. Zoghbi.)

A. Comparison of a normal spiny neuron from the caudate nucleus and a spiny neuron affected by Huntington disease. Note the marked recurving of terminal dendritic branches in the diseased neuron.

B. A pigmented dopaminergic neuron in the substantia nigra with a classic cytoplasmic inclusion (Lewy body). The circular cytoplasmic inclusion is surrounded by a clear halo. Recent electron-microscopic and biochemical evidence indicates that

the primary components of Lewy bodies are α -synuclein, ubiquitin, and abnormally phosphorylated neurofilaments that form a nonmembrane-bounded compacted skein in the cell body. Extracellular Lewy bodies occur following neuronal cell death and disintegration.

C. A neuron with a typical nuclear inclusion almost as large as the nucleolus.

D. Because spinocerebellar ataxia type 6 results from a repeat expansion in *CACNA1A*, the gene encoding a calcium channel, it is not surprising that affected neurons do not accumulate nuclear inclusions. *CACNA1A* labeling instead occurs diffusely throughout the cytoplasm.

Several Pathways Underlie the Pathogenesis of Neurodegenerative Diseases

Protein Misfolding and Degradation Contribute to Parkinson Disease

Proteins with expanded glutamine tracts and mutant α -synuclein accumulate in the neurons of patients and various animal models, indicating that these abnormal proteins are not degraded efficiently. Molecular chaperones, which facilitate cell protein refolding and degradation (see Chapter 4), are redistributed to the site of these protein aggregates.

The gradual accumulation of proteins with expanded glutamine tracts along with chaperones and components of the ubiquitin-proteasome degradation pathway, suggests that the glutamine tract expansion alters the folding state of the native protein, which in turn recruits the activity of the protein-folding and degradation machinery. When that machinery cannot process the protein, the protein molecules accumulate, eventually forming aggregates. Wild-type α -synuclein and ataxin-1 may have some tendency to misfold even in the absence of a mutation; when they are produced at sufficiently high levels the number of misfolded molecules increases, and their toxicity becomes apparent.

Evidence in support of this idea first came from studies in cell culture in which overproduction of chaperones both reduces protein aggregation and mitigates the toxicity of expanded glutamine tracts in proteins. In contrast, blocking the proteasome inhibits protein degradation and thus enhances aggregation and toxicity. Genetic studies in flies and mice provide even more compelling evidence. Overproduction of at least one chaperone, such as Hsp70, Hsp40, or tetratricopeptide protein 2, suppresses polyglutamine toxicity in *Drosophila* and mouse models of Parkinson disease and several different ataxias, whereas loss of chaperone function aggravates neurodegeneration (Figure 44–5).

The importance of the ubiquitin-proteasome pathway and protein degradation in the spinocerebellar ataxias is further supported by genetic modification in animal models. In a Drosophila model of SCA1, haploinsufficiency for ubiquitin, ubiquitin carrier enzymes, or a ubiquitin carboxyl-terminal hydrolase aggravates neurodegeneration. Loss of function of the E3 ubiquitin ligase Ube3a in mice exacerbates ataxin-1induced neurodegeneration, even though the Purkinje cells develop no nuclear inclusions. It appears that inclusions are part of the cell's attempt to sequester the mutant protein and thereby limit its toxic effects. Cells that are unable to form aggregates of the mutated proteins suffer the worst damage from polyglutamine toxicity. Indeed, the knock-in mouse models of spinocerebellar ataxia types 1 and 7 show conclusively that cells that form aggregates survive longer; cerebellar Purkinje cells, the prime targets in this disease, are the last to form nuclear aggregates.

Studies of Parkinson disease further underscore the importance of the ubiquitin-proteasome pathway and reveal additional parallels with the polyglutamine diseases. The *parkin* gene, mutated in Parkinson disease type 2, encodes an E3 ubiquitin ligase that has among its targets the O-glycosylated form of α -synuclein. Levels of this glycosylated form of α -synuclein are increased in brains of patients with deformed parkin despite the absence of Lewy bodies. This suggests that Lewy-body formation requires ubiquitination of α -synuclein, and again indicates that the misfolded protein is sequestered when it is not completely degraded.

How do misfolded α -synuclein or expanded glutamine tracts disrupt neuronal function? A protein that resists degradation or has an aberrant conformation might have its normal function in the cell enhanced, as happens with glutamine-expanded ataxin-1. Part of the gain of toxic function involves alterations in gene expression.

Protein Misfolding Triggers Pathological Alterations in Gene Expression

One of the key consequences of misfolding as a result of expanded glutamine tracts is alteration in gene expression. This was first suspected when it was real-

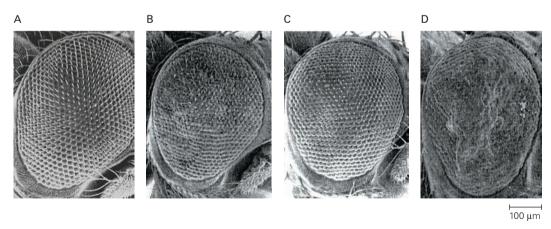

Figure 44–5 Polyglutamine-induced degeneration in the *Drosophila* eye and the effect of modifiers. (Images, used with permission, by J. Botas.)

- **D.** Absence of another heat-shock protein aggravates the polyglutamine-induced phenotype.

ized not only that most of the mutant proteins accumulate in the cell nucleus, but also that they interact with or affect the function of key transcriptional regulators. For example, CREB-binding protein interacts with huntingtin exon 1. Moreover, overproduction of polyglutamine proteins reduces levels of histone acetylation in cells, an effect that can be reversed by overproduction of CREB-binding protein.

Alterations in gene expression are among the earliest events in pathogenesis, occurring within days of expression of the mutant transgene in mouse models of SCA1 and Huntington disease. Many of the genes whose expression is altered are involved in Ca²⁺ homeostasis, synaptic transmission, and transduction of sensory events into neural signals. In fly models of SCA1 several modifiers of the neurodegenerative phenotype are transcriptional cofactors. Alterations in gene expression may also occur because of altered RNA processing or stability. Ataxin-1 binds RNAs in vitro, and several genetic modifiers in fly models of SCA1 encode proteins involved in RNA binding or processing.

Mitochondrial Dysfunction Exacerbates Neurodegenerative Disease

Evidence for mitochondrial dysfunction in polyglutamine disorders and Parkinson disease comes from morphological and functional studies. Lymphoblast mitochondria from patients with Huntington disease as well as brain mitochondria from a transgenic mouse model for Huntington disease have a lower membrane potential and depolarize at lower Ca²⁺ loads than do control mitochondria.

Several proteins implicated in Parkinson disease affect mitochondrial function and integrity. For example, in *Drosophila* the loss of PINK1 leads to mitochondrial dysfunction that can be rescued by parkin. LRRK2, which interacts with parkin, is localized in part to the outer mitochondrial membrane. Thus, given the functions and interactions of these proteins, mitochondrial dysfunction is likely to be a key contributor to the Parkinson disease phenotype.

Apoptosis and Caspase Modify the Severity of Neurodegeneration

Although animal studies of most neurodegenerative diseases have demonstrated that symptoms appear long before detectable cell death, loss of neurons is a hallmark of the end stage of all these disorders. Although many factors are implicated in the death of neurons, such as altered Ca²⁺ homeostasis

and decreased induction of neuronal survival factors (eg, brain-derived neurotrophic factor in Huntington disease), there is specific evidence that the caspase activity critical for apoptosis is a contributing factor in neurodegenerative diseases. Some of the polyglutamine proteins, such as huntingtin, AR, ataxin-3, and atrophin-1, are substrates for caspases in vitro. This raises the possibility that the proteases liberate the fragments of these proteins with expanded glutamine tracts. As discussed earlier, such fragments are even more damaging than the full-length protein.

Intranuclear huntingtin increases production of caspase-1 in cells; this could lead to apoptosis and caspase-3 activation. Hip-1, a protein that interacts with huntingtin, forms a complex that activates caspase-8. This process might be enhanced by the glutamine expansion in huntingtin, because Hip-1 binds less avidly to mutant huntingtin than to the wild-type protein. In *Drosophila* production of the anti-apoptotic protein p35 results in partial rescue of the pigment loss induced by mutant ataxin-3.

In summary, expansions of polyglutamine tracts as well as several missense mutations in proteins implicated in neurodegenerative diseases alter the host protein, leading to its accumulation or abnormal interactions. The neuronal dysfunction results from the downstream effects of such abnormal interactions (Figure 44–6).

Advances in Understanding the Molecular Basis of Neurodegenerative Diseases Are Opening Possibilities for Approaches to Therapeutic Intervention

The discovery of the genetic bases and pathogenic mechanisms of various neurodegenerative diseases gives us hope that therapies for these diseases will soon emerge.

Dopamine replacement therapy has so far been the only option for Parkinson disease and other conditions with parkinsonian features, but it is not ideal. Patients tend to develop tolerance and require higher and higher doses of the drugs. Side effects therefore become as troubling as the symptoms being treated. Patients with Huntington disease and spinocerebellar ataxia are in a worse state: There are no treatments that slow the progressive loss of motor coordination.

The identification of protein misfolding as a key step in pathogenesis has led investigators to search for drugs that safely induce chaperone activity and that can be tested in the various animal models. Geldanamycin, a drug known to activate heat-shock

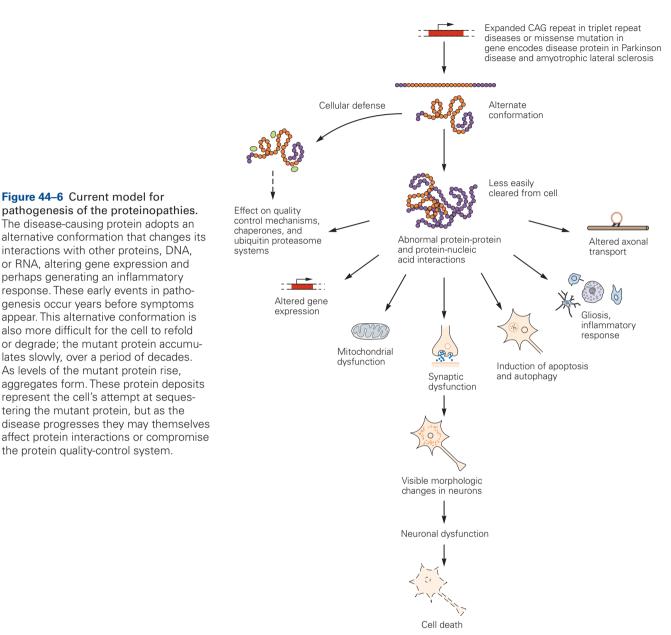

Figure 44-6 Current model for pathogenesis of the proteinopathies. The disease-causing protein adopts an alternative conformation that changes its interactions with other proteins, DNA, or RNA, altering gene expression and perhaps generating an inflammatory response. These early events in pathogenesis occur years before symptoms appear. This alternative conformation is also more difficult for the cell to refold or degrade; the mutant protein accumulates slowly, over a period of decades. As levels of the mutant protein rise, aggregates form. These protein deposits represent the cell's attempt at sequestering the mutant protein, but as the

the protein quality-control system.

chaperones, suppresses polyglutamine-induced protein aggregation and toxicity in cell culture. Because some glutamine-expanded proteins interact with or sequester CREB-binding protein, a protein with histone acetylase activity, inhibitors of histone deacetylase such as sodium butyrate and suberoylanilide hydroxamic acid have been used in mammalian cells, yeast cells, and Drosophila models expressing a polypeptide with an expanded glutamine tract. These treatments suppress cell death and improve the viability of cells of fruit flies—a very promising finding.

Cystamine, an inhibitor of the transglutaminase that is thought to promote protein aggregation, improves neuronal function. Moreover, caspase inhibitors enhance the survival of mice expressing an expanded glutamine tract in huntingtin exon 1. These results suggest that several pathways can be targeted for therapeutic intervention. Ideally, therapies would be targeted at some of the earliest pathogenic stages, at which neuronal dysfunction rather than cell death causes the neurological phenotype. Intervention at an early stage could prove beneficial clinically, for it might halt the disease

and even allow recovery of function. Indeed, in mouse models of Huntington disease and SCA1 in which expression of the mutant gene can be turned on and off, neuronal dysfunction is reversible. When expression of the transgene is turned off, the neurons have a chance to clear the mutant polyglutamine protein and regain normal activity.

Because most neurodegenerative diseases progress over a period of decades, pharmacological interventions that even slightly modulate one or more of the pathways described earlier could delay disease progression or modestly improve function, which would greatly enhance the quality of life for patients suffering from these devastating disorders.

An Overall View

The identification of genes causing several forms of Parkinson disease and the various polyglutamine neurodegenerative diseases has allowed the accurate diagnosis and classification of these clinically heterogeneous disorders. More importantly, studies in cell culture and model organisms have revealed a pathogenic mechanism common to all of these diseases: protein misfolding. Mutations that cause the respective proteins to adopt an altered conformation gradually induce neuronal dysfunction either because of abnormal protein interactions or because of intracellular protein accumulation and altered activity. The identification of pathways that mediate some of the pathogenic effects is likely to lead to the discovery of drugs that can first be tested in model animals and then applied in humans.

Painting of Yama, the Indian God of death, made in Tibet around the 17th century. In Tibetan Buddhism Yama protects people against emotional addictions such as lust and hate. While religion, mythology, and medicine have been invoked throughout history to explain our emotions and control our appetites, Buddhism has articulated particularly well the perils of human craving and the benefits of expanding the scope of the conscious mind. This is a detail of the full painting shown above. (Reproduced, with permission, from image copyright: the Metropolitan Museum of Art; image source: Art Resource, NY.)

The Unconscious and Conscious Processing of Neural Information

ANY ASPECTS OF BEHAVIOR, ESPECIALLY EMOTIONAL and homeostatic behaviors, are unconscious and instinctive. They are mediated almost reflexively by systems in subcortical brain regions that are concerned with feeding, drinking, temperature regulation, and sex.

Thus, as Sigmund Freud first pointed out in 1900, we experience emotional states not only consciously but also unconsciously. Many of these emotional states, particularly those involving fear, depend on the amygdala, a subcortical region of the limbic system. The cognitive elements in emotions, which we call *feeling states*, are thought to be mediated by pathways to the cerebral cortex that originate from the musculature of the body and the internal organs, on the one hand, and from the amygdala, on the other hand. In contrast, unconscious emotional states are thought to depend on autonomic, endocrine, and skeletal motor responses in subcortical parts of the nervous system, especially connections between the nuclei of the amygdala, the hypothalamus, and the brain stem. These unconscious responses can prepare the body for action and communicate internal emotional states to other individuals. An emerging realization in the neurobiology of emotion is that an unconscious representation of our emotional state by the amygdala can lead to a somatic response that often precedes our cognitive awareness—our feeling—of an emotional state. This conscious feeling state presumably involves the cerebral cortex, the outer layer of the brain. When the function of the cerebral cortex is temporarily disrupted, as in an epileptic convulsion, we lose all sense of emotion and feeling, and commonly, we lose consciousness.

We begin our consideration of these systems with the brain stem, a structure critical for wakefulness and conscious attention on the one hand and sleep on the other. Thus, the significance of this small region of the central nervous system—located between the spinal cord and the diencephalon—is disproportionate to its size. Damage to the brain stem can profoundly affect motor and sensory processes because the brain stem contains all of the ascending tracts that bring sensory information from the surface of the body to the cerebral cortex and all the descending tracts from the cerebral cortex that deliver motor commands to the spinal cord. Damage to the brain stem also can affect consciousness and sleep because the brain stem contains the locus ceruleus, a center thought to be crucial for attention and therefore for many cognitive functions. In fact, fully half of all noradrenergic neurons of the brain are clustered together in this small nucleus. Finally, the brain stem contains neurons that control respiration

and heartbeat as well as nuclei that give rise to most of the cranial nerves that innervate the head and neck.

Six neurochemical modulatory systems in the brain stem regulate sensory, motor, and arousal systems. The dopaminergic pathways that connect the midbrain to the limbic system and cortex are particularly important because they are involved in reinforcement of behavior and therefore contribute to motivational state and learning. Addictive drugs such as nicotine, alcohol, opiates, and cocaine are thought to produce their actions by co-opting the same neural pathways that positively reinforce behaviors essential for survival. Other modulatory transmitters regulate sleep and wakefulness, in part by controlling information flow between the thalamus and cortex. Disorders of electrical excitation in corticothalamic circuits can result in seizures and epilepsy.

Rostral to the brain stem lies the hypothalamus, one of whose functions is to maintain the stability of the internal environment by keeping physiological variables within the limits favorable to vital bodily processes. Homeostatic processes in the nervous system have profound consequences for behavior that have intrigued many of the founders of modern physiology, including Claude Bernard, Walter B. Cannon, and Walter Hess. Neurons controlling the internal environment are concentrated in the hypothalamus, a small area of the diencephalon that comprises less than 1% of the total volume of the brain. The hypothalamus, with closely linked structures in the brain stem and limbic system, acts directly on the internal environment through its control of the endocrine system and autonomic nervous system to achieve goal-directed behavior. It acts indirectly through its connections to higher brain regions to control emotional and motivational states. In addition to regulating specific motivated behaviors, the hypothalamus, together with the brain stem below and the cerebral cortex above, maintains a general state of arousal, which ranges from excitement and vigilance to drowsiness and stupor.

Embryonic Cranial Nerve Nuclei Have a Segmental Organization

The Organization of the Brain Stem and Spinal Cord Differs in Three Important Ways

Neuronal Ensembles in the Brain Stem Reticular Formation Coordinate Reflexes and Simple Behaviors Necessary for Homeostasis and Survival

Cranial Nerve Reflexes Involve Mono- and Polysynaptic Brain Stem Relays

Pattern Generator Neurons Coordinate Stereotypic and Autonomic Behaviors

A Complex Pattern Generator Regulates Breathing

An Overall View

IN PRIMITIVE VERTEBRATES—REPTILES, amphibians, and fish—the forebrain is only a small part of the brain and is devoted mainly to olfactory processing and to the integration of autonomic and endocrine function with the basic behaviors necessary for survival. These basic behaviors include feeding, drinking,

sexual reproduction, sleep, and emergency responses. Although we are accustomed to thinking that human behavior originates mainly in the forebrain, many complex responses, such as feeding—the coordination of chewing, licking, and swallowing—are actually made up of relatively simple, stereotypic motor responses governed by ensembles of neurons in the brain stem.

The importance of this pattern of organization in human behavior is clear from observing infants born without a forebrain (hydrancephaly). Hydrancephalic infants are surprisingly difficult to distinguish from normal babies. They cry, smile, suckle, and move their eyes, face, arms, and legs. As these sad cases illustrate, the brain stem can organize virtually all of the behavior of the newborn.

In this chapter we examine the role of the brain stem in reflex behavior. We also review the cranial nerves, their origin in the brain stem, as well as the ensembles of local circuit neurons that organize the simple behaviors of the face and head.

The brain stem is the rostral continuation of the spinal cord and its motor and sensory components are similar in structure to that of the spinal cord. But the portions of the brain stem that control the cranial nerves are much more complex than the corresponding parts of the spinal cord that control the spinal nerves because cranial nerves mediate more complex behaviors. The core of the brain stem, the *reticular formation*, is homologous to the intermediate gray matter of the spinal cord but is also more complex. Like the spinal cord, the reticular formation contains ensembles of local-circuit interneurons that generate motor and autonomic patterns and coordinate reflexes and simple behaviors. In addition, it contains clusters of

dopaminergic, noradrenergic, and other modulatory neurons that act to optimize the functions of the nervous system. The modulatory actions of these nuclei are described in the next chapter.

The Cranial Nerves Are Homologous to the Spinal Nerves

Because the spinal nerves reach only as high as the first cervical vertebra, the cranial nerves provide the somatic and visceral sensory and motor innervation for the head. Two cranial nerves, the glossopharyngeal and vagus nerves, also supply visceral sensory and motor innervation of the neck, chest, and most of the abdominal organs with the exception of the pelvis. Unlike the spinal nerves, which supply all sensory and motor functions for specific body segments, each cranial nerve is associated with one or more functions and may therefore overlap the physical territory of another cranial nerve.

Assessment of the cranial nerves is an important part of the neurological examination (see Appendix B) because abnormalities of function can pinpoint a site in the brain stem that has been damaged. Therefore, it is important to know the origins of the cranial nerves, their intracranial course, and where they exit from the skull.

The cranial nerves are traditionally numbered I through XII in rostrocaudal sequence. Cranial nerves I and II enter at the base of the forebrain. The other cranial nerves arise from the brain stem at characteristic locations (Figure 45–1). All but one exit from the ventral surface of the brain stem. The exception is the trochlear (IV) nerve, which leaves the midbrain from its dorsal surface just behind the inferior colliculus and wraps around the lateral surface of the brain stem to join the other cranial nerves concerned with eye movements. The cranial nerves with sensory functions (V, VII, VIII, IX, and X) have associated sensory ganglia that operate much as dorsal root ganglia do for spinal nerves. These ganglia are located along the course of individual nerves as they enter the skull.

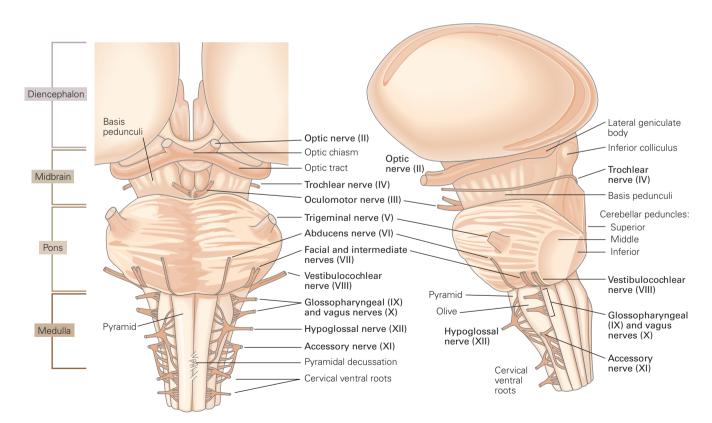

Figure 45–1 The origins of cranial nerves in the brain stem (ventral and lateral views). The olfactory (I) nerve is not shown because it terminates in the olfactory bulb in the

forebrain. All of the cranial nerves except one emerge from the ventral surface of the brain; the trochlear (IV) nerve originates from the dorsal surface of the midbrain.

The olfactory (I) nerve, which is associated with the forebrain, is described in detail in Chapter 32; the optic (II) nerve, which is associated with the diencephalon, is described in Chapters 25 and 26. The spinal accessory (XI) nerve can be considered a cranial nerve anatomically but actually is a spinal nerve originating from the higher cervical motor rootlets. It runs up into the skull before exiting through the jugular foramen to innervate the trapezius and sternocleidomastoid muscles in the neck.

Cranial Nerves Mediate the Sensory and Motor Functions of the Face and Head and the Autonomic Functions of the Body

The ocular motor nerves—the oculomotor (III), trochlear (IV), and abducens (VI) nerves—control movements of the eyes. The abducens nerve has the simplest action; it contracts the lateral rectus muscle to move the globe laterally. The trochlear nerve also innervates a single muscle, the superior oblique, but its action both depresses the eye and rotates it inward, depending on the eye's position. The oculomotor nerve supplies all of the other muscles of the orbit, including the retractor of the lid. It also provides the parasympathetic innervation responsible for pupillary constriction in response to light and accommodation of the lens for near vision. The ocular motor system is considered in detail in Chapter 39.

The *trigeminal* (V) *nerve* is a mixed nerve (containing both sensory and motor axons) that leaves the brain stem in two roots. The motor root innervates the muscles of mastication (the masseter, temporalis, and pterygoids) and a few muscles of the palate (tensor veli palatini), inner ear (tensor tympani), and upper neck (mylohyoid and anterior belly of the digastric muscle).

The sensory fibers arise from neurons in the trigeminal ganglion, located at the floor of the skull in the middle cranial fossa, the central division of the skull, adjacent to the sella turcica, which houses the pituitary gland.

Three branches emerge from the trigeminal ganglion. The *ophthalmic division* (V_1) runs with the ocular motor nerves through the superior orbital fissure (Figure 45–2A) to innervate the orbit, nose, and forehead and scalp back to the vertex of the skull (Figure 45–3). Some fibers from this division also innervate the meninges and blood vessels of the anterior and middle intracranial fossas. The *maxillary division* (V_2) runs through the round foramen of the sphenoid bone to innervate the skin over the cheek and the upper portion of the oral cavity. The *mandibular division* (V_3), which also contains the motor axons of the trigeminal

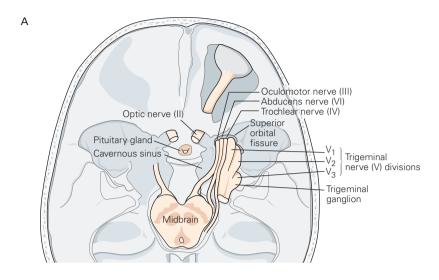

nerve, leaves the skull through the oval foramen of the sphenoid bone. It innervates the skin over the jaw, the area above the ear, and the lower part of the oral cavity, including the tongue.

Complete trigeminal sensory loss results in numbness of the entire face and the inside of the mouth. One-sided trigeminal motor weakness does not cause much weakness of jaw closure because the muscles of mastication on either side are sufficient to close the jaw. Nevertheless, the jaw tends to deviate toward the side of the lesion when the mouth is opened because the internal pterygoid muscle on the opposite side, when unopposed, pulls the jaw toward the weak side.

The facial (VII) nerve is also a mixed nerve. Its motor root supplies the muscles of facial expression as well as the stapedius muscle in the inner ear, stylohyoid muscle, and posterior belly of the digastric muscle in the upper neck. The sensory root runs as a separate bundle, the nervus intermedius, through the internal auditory canal and arises from neurons in the geniculate ganglion, located near the middle ear. Distal to the geniculate ganglion the sensory fibers diverge from the motor branch. Some innervate skin of the external auditory canal whereas others form the chorda tympani, which joins the lingual nerve and conveys taste sensation from the anterior two-thirds of the tongue. The autonomic component of the facial nerve includes parasympathetic fibers that travel through the motor root to the sphenopalatine and submandibular ganglia, which innervate lacrimal and salivary glands (except the parotid gland) and the cerebral vasculature.

The facial nerve may suffer isolated injury in Bell's palsy, a common complication of certain viral infections. Early on the patient may complain mainly of the face pulling toward the unaffected side because of the weakness of the muscles on the side of the lesion. Later the ipsilateral corner of the mouth droops, food falls out of the mouth, and the eyelids no longer close on that side. Loss of blinking may result in drying and injury to the cornea. The patient may complain that sound has a booming quality in the ipsilateral ear because the stapedius muscle fails to tense the ossicles in response to a loud sound (the stapedial reflex). Taste may also be lost on the anterior two-thirds of the tongue on the ipsilateral side. If the Bell's palsy is caused by a herpes zoster infection of the geniculate ganglion, small blisters may form in the outer ear canal, the ganglion's cutaneous sensory field.

The *vestibulocochlear* (VIII) *nerve* contains two main bundles of sensory axons from two ganglia. Fibers from the vestibular ganglion relay sensation of angular and linear acceleration from the semicircular canals, utricle, and saccule in the inner ear. Fibers from

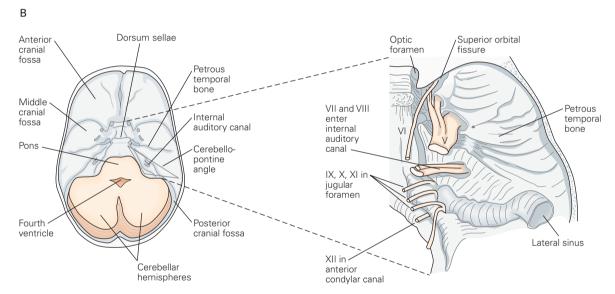

Figure 45–2 The cranial nerves exit the skull in groups.

A. Cranial nerves II, III, IV, V, and VI exit the skull near the pituitary fossa. The optic (III) nerve enters the optic foramen, but the oculomotor (IIII), trochlear (IV), and abducens (VI) nerves, and the first division of the trigeminal (V) nerve leave through the superior orbital fissure. The second and third divisions of the trigeminal nerve exit through the round and oval foramina, respectively.

B. In the posterior fossa the facial (VII) and vestibulocochlear (VIII) nerves exit through the internal auditory canal, whereas the glossopharyngeal (IX), vagus (X), and accessory (XI) nerves leave through the jugular foramen. The hypoglossal nerve (XII) has its own foramen.

the cochlear ganglion relay information from the cochlea concerning sound. A vestibular schwannoma, one of the most common intracranial tumors, may form along the vestibular component of cranial nerve VIII as it runs within the internal auditory meatus. Most patients complain only about hearing loss, as the brain

is usually able to adapt to the gradual loss of vestibular input from one side.

The glossopharyngeal (IX) nerve and vagus (X) nerve are mixed but are predominantly autonomic. These closely related nerves transmit sensory information from the pharynx and upper airway as well as taste

from the posterior third of the tongue and oral cavity. The glossopharyngeal nerve transmits visceral information from the neck (for example, information on blood oxygen and carbon dioxide from the carotid body, and arterial pressure from the carotid sinus), whereas the vagus nerve transmits visceral information from the thoracic and abdominal organs except for the distal colon and pelvic organs. Both nerves include parasympathetic motor fibers. The glossopharyngeal nerve provides parasympathetic control of the parotid salivary gland, whereas the vagus nerve innervates the rest of the internal organs of the neck, thorax, and abdomen. The glossopharyngeal nerve innervates only one muscle of the palate, the stylopharyngeus, which raises and dilates the pharynx. The remaining striated muscles of the larynx and pharynx are under control of the vagus nerve.

Because many of the functions of nerves IX and X are bilateral and partially overlapping, unilateral injury of nerve IX may be difficult to detect. Patients with unilateral cranial nerve X injury are hoarse, because one vocal cord is paralyzed, and may have some difficulty swallowing. Examination of the oropharynx shows weakness and numbness of the palate on one side.

The *spinal accessory* (XI) *nerve* is purely motor and originates from motor neurons in the upper cervical spinal cord. It innervates the trapezius and sternocleidomastoid muscles on the same side of the body. Because the mechanical effect of the sternocleidomastoid is to turn the head toward the opposite side, an

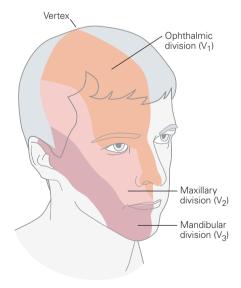

Figure 45–3 The three sensory divisions of the trigeminal (V) nerve innervate the face and scalp.

injury of the left nerve causes weakness in turning the head to the right. A lesion of the cerebral cortex on the left will cause weakness of muscles on the entire right side of the body except for the sternocleidomastoid; instead, the ipsilateral sternocleidomastoid will be weak (because the left cerebral cortex is concerned with interactions with the right side of the world).

The *hypoglossal* (XII) *nerve* is also purely motor, innervating the muscles of the tongue. When the nerve is injured, for example during surgery for head and neck cancer, the tongue atrophies on that side. The muscle fibers exhibit twitches of muscle fascicles (fasciculations), which may be seen clearly through the thin mucosa of the tongue.

Cranial Nerves Leave the Skull in Groups and Often Are Injured Together

In assessing dysfunction of the cranial nerves it is important to determine whether the injury is within the brain or further along the course of the nerve. As cranial nerves leave the skull in groups through specific foramina, damage at these locations can affect several nerves.

The cranial nerves concerned with orbital sensation and movement of the eyes (III, IV, VI, and the ophthalmic division of the trigeminal nerve, V₁) are gathered together in the *cavernous sinus*, along the lateral margins of the sella turcica, and then exit the skull through the *superior orbital fissure* adjacent to the optic foramen (Figure 45–2A). Tumors in this region, such as those arising from the pituitary gland, often make their presence known first by pressure on these nerves or the adjacent optic chiasm.

Cranial nerves VII and VIII exit the brain stem at the *cerebellopontine angle*, the lateral corner of the brain stem at the juncture of the pons, medulla, and cerebellum (Figure 45–2B), and then leave the skull through the internal auditory meatus. A common tumor of the cerebellopontine angle is the vestibular schwannoma (sometimes erroneously called an "acoustic neuroma"), which derives from Schwann cells in the vestibular component of nerve VIII. If the tumor is large, it may not only impair the function of nerves VII and VIII but may also press on nerve V near its site of emergence from the middle cerebellar peduncle, causing facial numbness, or compress the cerebellum or its peduncles on the same side, causing ipsilateral clumsiness.

The lower cranial nerves (IX, X, and XI) exit through the *jugular foramen* (Figure 45–2B) and are vulnerable to compression by tumors at that site. Nerve XII leaves the skull through its own (hypoglossal) foramen

and is generally not affected by tumors located in the adjacent jugular foramen, unless the tumor becomes quite large. If nerve XI is spared, the injury is generally within or near the brain stem rather than near the jugular foramen.

Cranial Nerve Nuclei in the Brain Stem Are Organized on the Same Basic Plan As Are Sensory and Motor Regions of the Spinal Cord

Cranial nerve nuclei are organized in rostrocaudal columns that are homologous to the sensory and motor laminae of the spinal cord (see Chapters 22 and 34). This pattern is best understood from the developmental plan of the caudal neural tube that gives rise to the brain stem and spinal cord.

The transverse axis of the embryonic caudal neural tube is subdivided into alar (dorsal) and basal (ventral) plates by the sulcus limitans, a longitudinal groove along the lateral walls of the central canal, fourth ventricle, and cerebral aqueduct (Figure 45–4). The alar plate forms the sensory components of the dorsal horn of the spinal cord, whereas the basal plate forms the motor components of the ventral horn. The intermediate gray matter is made up primarily of the interneurons that coordinate spinal reflexes and motor responses.

The brain stem shares this basic plan. As the central canal of the spinal cord opens into the fourth ventricle, the walls of the neural tube are splayed outward so that the dorsal sensory structures (derived from the alar plate) are displaced laterally whereas the ventral motor structures (derived from the basal plate) remain more medial. The nuclei of the brain stem are divided into *general nuclei*, which serve functions similar to those of the spinal cord laminae, and *special nuclei*, which serve functions unique to the head (such as hearing, balance, taste, and control of the branchial musculature).

Adult Cranial Nerve Nuclei Have a Columnar Organization

Overall, the brain stem nuclei on each side are organized in six rostrocaudal columns, three of sensory nuclei and three of motor nuclei (Figure 45–5). These are considered below, in dorsolateral to ventromedial sequence. The columns are discontinuous—the nuclei are not packed solidly along the rostrocaudal axis of the brain stem. Nuclei with similar functions (sensory or motor, somatic or visceral) have similar dorsolateral-ventromedial positions at each level of the brain stem.

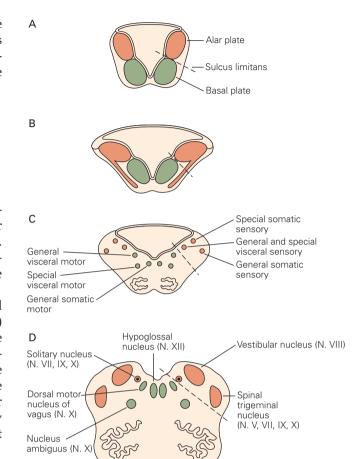

Figure 45–4 The developmental plan of the brain stem is the same general plan as that of the spinal cord.

A. The neural tube is divided into a dorsal sensory portion (the alar plate) and a ventral motor portion (the basal plate) by a longitudinal groove, the sulcus limitans.

B–D. During development the sensory and motor cell groups migrate into their adult positions, but largely retain their relative locations. In maturity (D) the sulcus limitans (dashed line) is still recognizable in the walls of the fourth ventricle and the cerebral aqueduct, demarcating the border between dorsal sensory structures (orange) and ventral motor structures (green). The section in D is from the rostral medulla.

Within each motor nucleus, motor neurons for an individual muscle are also arranged in a cigar-shaped longitudinal column. Thus each motor nucleus in cross section forms a mosaic map of the territory that is innervated. For example, in a cross section through the facial nucleus the clusters of neurons that innervate the different facial muscles form a topographic map of the face.

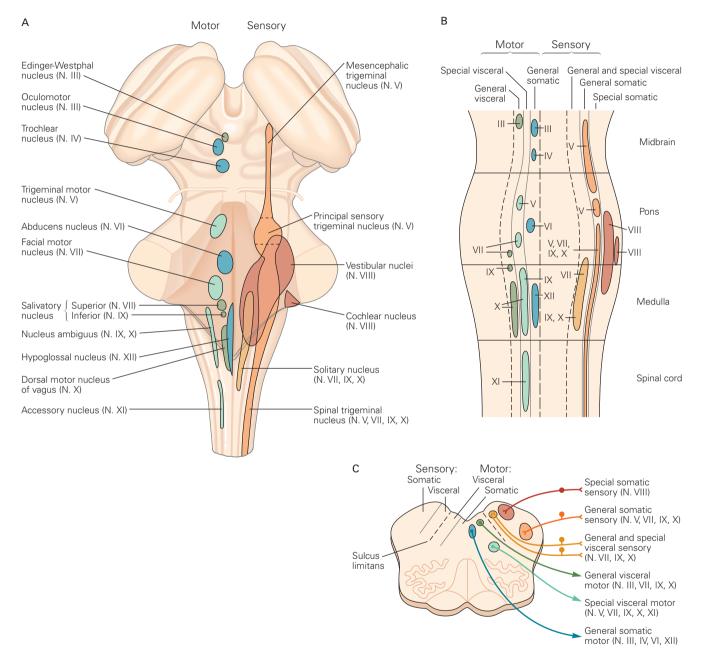

Figure 45–5 Adult cranial nerve nuclei are organized in six functional columns on the rostrocaudal axis of the brain stem.

A. This dorsal view of the human brain stem shows the location of the cranial nerve sensory nuclei (right) and motor nuclei (left).

- **B.** A schematic view of the functional organization of the motor and sensory columns.
- C. The medial-lateral arrangement of the cranial nerve nuclei is shown in a cross section at the level of the medulla (compare with Figure 45–4).

General Somatic Sensory Column

The general somatic sensory column occupies the most lateral region of the alar plate and includes the trigeminal sensory nuclei (N. V). The spinal trigeminal nucleus is a continuation of the dorsal-most laminae of the spinal dorsal horn (Figure 45-5A) and is sometimes called the medullary dorsal horn. Its outer surface is covered by the spinal trigeminal tract, a direct continuation of Lissauer's tract of the spinal cord (see Chapter 24), thus allowing some cervical sensory fibers to reach the trigeminal nuclei and some trigeminal sensory axons to reach the dorsal horn in upper cervical segments. This arrangement allows dorsal horn sensory neurons to have a range of inputs that are much broader than that of individual spinal or trigeminal segments, and ensures the integration of trigeminal and upper cervical sensory maps.

The spinal trigeminal nucleus receives sensory axons from the trigeminal ganglion (N. V) and from all cranial nerve sensory ganglia concerned with pain and temperature in the head, including geniculate ganglion (N. VII) neurons that relay information from the external auditory meatus, petrosal ganglion (N. IX) cells that convey information from the posterior part of the palate and tonsillar fossa, and nodose ganglion (N. X) axons that relay information from the posterior wall of the pharynx. The spinal trigeminal nucleus thus represents the entire oral cavity as well as the surface of the face.

The somatotopic organization of the afferent fibers is inverted: The forehead is represented ventrally and the oral region dorsally. Axons from the spinal trigeminal nucleus descend on the same side of the brain stem into the upper spinal cord, where they cross the midline in the anterior commissure with spinothalamic axons and join the opposite spinothalamic tract. (For this reason, upper cervical spinal cord injury may cause facial numbness.) The trigeminothalamic axons then ascend back through the brain stem, providing inputs to brain stem nuclei for reflex motor and autonomic responses in addition to carrying pain and temperature information to the thalamus.

The principal sensory trigeminal nucleus lies in the mid pons just lateral to the trigeminal motor nucleus. It receives the axons of neurons in the trigeminal ganglion concerned with position sense and fine touch discrimination, the same types of sensory information carried from the rest of the body by the dorsal columns. The axons from this nucleus are bundled with those from the dorsal column nuclei in the medial lemniscus, through which they ascend to the ventroposterior medial thalamus.

An additional component of the trigeminal sensory system, located at the midbrain level in the lateral surface of the periaqueductal gray matter, is the *mesencephalic trigeminal nucleus*, which relays mechanosensory information from the muscles of mastication and the periodontal ligaments. The large cells of this nucleus are not central neurons but primary sensory ganglion cells that derive from the neural crest and, unlike their relatives in the trigeminal ganglion, migrate into the brain during development. The central branches of the axons of these pseudo-unipolar cells contact motor neurons in the trigeminal motor nucleus, providing monosynaptic feedback to the jaw musculature, critical for the precise control of chewing movements.

Special Somatic Sensory Column

The special somatic sensory column has inputs from the acoustic and vestibular nerves and develops from the intermediate region of the alar plate. The *cochlear nuclei* (N. VIII), which lie at the lateral margin of the brain stem at the pontomedullary junction, receive auditory afferents from the spiral ganglion of the cochlea. The output of these nuclei is relayed through the pons to the superior olivary and trapezoid nuclei and bilaterally on to the inferior colliculus (see Chapter 31). The *vestibular nuclei* (N. VIII) are more complex. They include four distinct cell groups that relay information from the vestibular ganglion to various motor sites in the brain stem, cerebellum, and spinal cord concerned with maintaining balance and coordination of eye and head movements (see Chapter 40).

Visceral Sensory Column

The visceral sensory column is concerned with special visceral information (taste) and general visceral information from the facial (VII), glossopharyngeal (IX), and vagus nerves (X). It is derived from the most medial tier of neurons in the alar plate. All of the afferent axons terminate in the *nucleus of the solitary tract*. The solitary tract is analogous to the spinal trigeminal tract or Lissauer's tract, bundling afferents from different cranial nerves as they course rostrocaudally along the length of the nucleus. As a result, visceral sensory information from different afferent nerves produces a unified visceral sensory map of the body in the nucleus.

Special visceral afferents carrying taste information from the anterior two-thirds of the tongue reach the nucleus of the solitary tract through the chorda tympani branch of the facial nerve, whereas those from the posterior parts of the tongue and oral cavity arrive through the glossopharyngeal and vagus nerves. These afferents terminate in roughly somatotopic fashion in the anterior third of the nucleus of the solitary tract. General visceral afferents are relayed through the glossopharyngeal and vagus nerves. Those from the rest of the gastrointestinal tract (down to the transverse colon) terminate in the middle portion of the solitary nucleus in topographic order, whereas those from the cardiovascular and respiratory systems terminate in the caudal and lateral portions.

The solitary nucleus projects directly to parasympathetic and sympathetic preganglionic motor neurons in the medulla and spinal cord that mediate various autonomic reflexes, as well as to parts of the reticular formation that coordinate autonomic and respiratory responses. Most ascending projections from the viscera to the forebrain are relayed through the parabrachial nucleus in the pons, although some reach the forebrain directly from the solitary nucleus. Together the solitary and parabrachial nuclei supply visceral sensory information to the hypothalamus, basal forebrain, amygdala, thalamus, and cerebral cortex.

General Visceral Motor Column

All motor neurons initially develop adjacent to the floor plate, a longitudinal strip of non-neuronal cells at the ventral midline of the neural tube (see Chapter 52). Neurons fated to become the three types of brain stem motor neurons migrate dorsolaterally, settling in three distinct rostrocaudal columns. The neurons that form the general visceral motor column migrate to the most lateral region of the basal plate, just medial to the sulcus limitans.

The *Edinger-Westphal nucleus* (N. III) lies next to the oculomotor complex just below the floor of the cerebral aqueduct. It contains preganglionic neurons that control pupillary constriction and lens accommodation through the ciliary ganglion.

The superior salivatory nucleus (N. VII) lies just dorsal to the facial motor nucleus and comprises parasympathetic preganglionic neurons that innervate the sublingual and submandibular salivary glands and the lacrimal glands and intracranial circulation through the sphenopalatine and submandibular parasympathetic ganglia.

Parasympathetic preganglionic neurons associated with the gastrointestinal tract form a column at the level of the medulla just dorsal to the hypoglossal nucleus and ventral to the nucleus of the solitary tract. At the most rostral end of this column is the *inferior*

salivatory nucleus (N. IX) comprising the preganglionic neurons that innervate the parotid gland through the otic ganglion. The rest of this column constitutes the dorsal motor vagal nucleus (N. X). Most of the preganglionic neurons in this nucleus innervate the gastrointestinal tract below the diaphragm; a few are cardiomotor neurons.

The *nucleus ambiguus* (N. X) is a cluster of neurons that runs the rostrocaudal length of the ventrolateral medulla and contains parasympathetic preganglionic neurons that innervate thoracic organs, including the esophagus, heart, and respiratory system, as well as special visceral motor neurons that innervate the striated muscle of the larynx and pharynx, and neurons that generate respiratory motor patterns (see below). The parasympathetic preganglionic neurons are organized in topographic fashion, with the esophagus represented most rostrally and dorsally.

Special Visceral Motor Column

The special visceral motor column includes motor nuclei that innervate muscles derived from the branchial (pharyngeal) arches. Because these arches are homologous to the gills in fish, the muscles are considered special visceral muscles, even though they are striated in mammals. During development these cell groups migrate to an intermediate position in the basal plate and are eventually located ventrolaterally in the tegmentum. The *trigeminal motor nucleus* (N. V) lies at midpontine levels and innervates the muscles of mastication. Associated with it are the *accessory trigeminal nuclei* that innervate the tensor tympani, tensor veli palatini, and mylohyoid muscles, and the anterior belly of the digastric muscle.

The facial motor nucleus (N. VII) lies caudal to the trigeminal motor nucleus at the level of the caudal pons and innervates the muscles of facial expression. During development facial motor neurons migrate medially and rostrally around the medial margin of the abducens nucleus before turning laterally, ventrally, and caudally toward their definitive location at the pontomedullary junction (Figure 45–6A). This sinuous course of the axons forms the *internal genu of the facial nerve*. The adjacent accessory facial motor nuclei innervate the stylohyoid and stapedius muscles and the posterior belly of the digastric muscle.

The nucleus ambiguus contains branchial motor neurons with axons that run in the glossopharyngeal and vagus nerves. These neurons innervate the striated muscles of the larynx and pharynx. During development these motor neurons migrate into the ventrolateral

medulla, and as a consequence their axons form a hairpin loop within the medulla, similar to those of the facial motor axons.

General Somatic Motor Column

The neurons of the somatic motor column migrate the least during development, remaining close to the ventral midline. The *oculomotor nucleus* (N. III) lies at the midbrain level; it consists of five rostrocaudal columns of motor neurons innervating the medial, superior, and inferior rectus muscles, the inferior oblique muscle, and the levator of the eyelids. The motor neurons for the medial and inferior rectus and inferior oblique muscles are on the same side of the brain stem as the nerve exits, whereas those for the superior rectus are on the opposite side. The levator motor neurons are bilateral.

The *trochlear nucleus* (N. IV), which innervates the trochlear muscle, lies at the midbrain/rostral pontine level also on the opposite side of the brain stem from which the nerve exits. The *abducens nucleus* (N. VI), which innervates the lateral rectus muscle, is located at the midpontine level. The *hypoglossal nucleus* (N. XII) at the caudal end of the medulla consists of several columns of neurons, each of which innervates a single muscle of the tongue.

Embryonic Cranial Nerve Nuclei Have a Segmental Organization

Although the sensory and motor nuclei in the adult hindbrain are organized rostrocaudally, the arrangement of neurons at each level derives from a strikingly segmental pattern in the early embryo. Before neurons appear, the future hindbrain region of the neural plate becomes subdivided into a series of eight segments of approximately equal size, known as *rhombomeres* (Figure 45–6A).

Each rhombomere develops a similar set of differentiated neurons, as if the hindbrain is made up of series of modules. The even-numbered rhombomeres differentiate ahead of the odd-numbered ones. This is most clearly seen in the branchial (special visceral) motor neurons, which are readily identified early in development. Rhombomeres 2, 4, and 6 form the branchial motor nuclei of the trigeminal, facial, and glossopharyngeal nerves, respectively. Later, rhombomeres 3, 5, and 7 contribute motor neurons to these nuclei; in each case the axons of individual motor neurons extend rostrally as they join those of their even-numbered neighbor. At this developmental stage each of these nuclei

is composed of homologous neurons derived from two adjacent segments. This early transverse segmental organization changes as rhombomere boundaries disappear and the dorsolateral migration of the cell bodies aligns the cells into rostrocaudal columns. The migration of the facial motor neurons of rhombomere 4 around the abducens nucleus (Figure 45–6A) generates the internal genu of the facial nerve.

The combination of the neurons of two rhombomeres into a single cranial nerve nucleus also corresponds to the relationship of the rhombomeres with the branchial arch muscles that are the targets of these motor neurons. For example, rhombomeres 2 and 3 (trigeminal) register with branchial arch 1 (mandibular), which forms the muscles of mastication; rhombomeres 4 and 5 (facial) register with branchial arch 2 (hyoid), which forms the muscles of facial expression (Figure 45–6A). Furthermore, neural crest cells from each rhombomere migrate into the corresponding branchial arches where they provide positional cues that determine the development and identity of the arch muscles.

The Organization of the Brain Stem and Spinal Cord Differs in Three Important Ways

One major difference between the organization of the brain stem and that of the spinal cord is that the long ascending and descending sensory tracts that run along the outside of the spinal cord are incorporated within the interior of the brain stem. Thus the ascending sensory tracts (the medial lemniscus and spinothalamic tract) run through the reticular formation of the brain stem as do the auditory, vestibular, and visceral sensory pathways.

A second major difference is that, in the brain stem, the cerebellum and its associated pathways form additional structures that are superimposed on the basic plan of the spinal cord. Fibers of the cerebellar tracts and nuclei are bundled with those of the pyramidal and extrapyramidal motor systems to form a large ventral portion of the brain stem. Thus, from the midbrain to the medulla the brain stem is divided into a dorsal portion, the tegmentum, which follows the basic segmental plan of the spinal cord, and a ventral portion, which contains the structures associated with the cerebellum and the descending motor pathways. At the level of the midbrain the ventral (motor) portion includes the cerebral peduncles, substantia nigra, and red nuclei. The base of the pons includes the pontine nuclei, corticospinal tract, and middle cerebellar peduncle. In the medulla the ventral motor structures include the pyramidal tracts and inferior olivary nuclei.

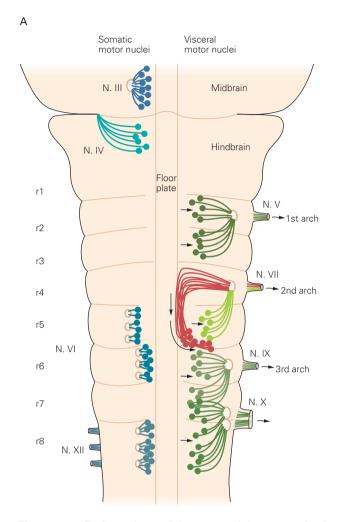

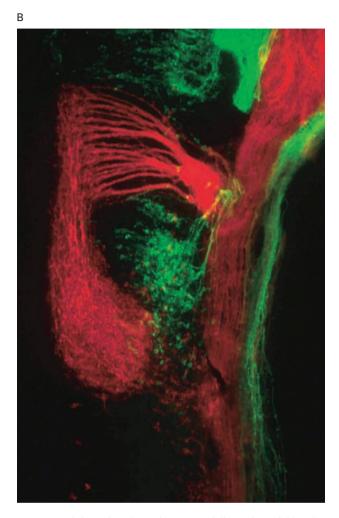

Figure 45–6 Embryonic cranial nerve nuclei are organized segmentally.

A. In the developing hindbrain (seen here from the ventral side) special and general visceral motor neurons form in each hindbrain segment (rhombomere) except rhombomere 1 (r1). Each special visceral motor nucleus comprises neurons in two rhombomeres: the trigeminal nucleus is formed by neurons in r2 and r3, the facial nucleus by neurons in r4 and r5, the glossopharyngeal nucleus by neurons in r6 and r7, and the motor nuclei of the vagus by neurons in r7 and r8. Axons of neurons in each of these nuclei course laterally within the brain, leaving the brain through exit points in the lateral neuroepithelium (of r2, r4, r6, and r7) and running together outside the brain to form the respective cranial motor nerves (V, VII, IX, X). The trigeminal (V) nerve innervates muscles in the 1st branchial arch, the facial (VII) nerve innervates muscles in the 2nd branchial arch, and the glossopharyngeal (IX) nerve innervates muscles in the 3rd branchial arch.

All of the visceral motor neurons (green) develop initially next to the floor plate at the ventral midline; after extending their axons toward their respective exit points, the cell bodies then migrate laterally (arrows). Exceptions are the facial motor neurons formed in r4 (red); the cell bodies, after extending their

axons toward the exit point, migrate caudally to the axial level of r6 before migrating laterally.

General somatic motor neurons (blue) are formed in r1 (trochlear nucleus), r5 and r6 (abducens nucleus), and r8 (hypoglossal nucleus). The cell bodies of these neurons remain close to their place of birth, next to the floor plate. The axons of abducens and hypoglossal neurons exit the brain directly, without coursing laterally. The axons of trochlear neurons (light blue) extend laterally and dorsally within the brain until, caudal to the inferior colliculus, they turn medially, decussate, and exit near the midline of the opposite side.

B. The brain stem of a mouse embryo in which fluorescent dyes label cranial nerve VII motor neurons. A red-fluorescing dye fills the cell bodies of facial motor neurons via retrograde transport from the motor root of the facial nerve. These neurons develop initially in r4 and then migrate posteriorly, alongside the floor plate, to r6 (see red neurons in part A). A green-fluorescing dye fills the cell bodies of general visceral motor neurons in r5 (see light green neurons in part A) via retrograde transport from the root of the intermediate nerve (sensory and preganglionic general visceral motor axons). (Micrograph reproduced, with permission, from Dr. Ian McKay.)

A third major difference is that, although the hindbrain is segmented into rhombomeres during development, there is no clear repeating pattern in the adult brain. In contrast, the spinal cord is not segmented during development but the final pattern consists of repeating segments. The prominent ladder-like arrays of ventral root axons and dorsal root ganglia suggest that segmentation is imposed by a polarizing effect of the adjacent somites into which they migrate—in each somite the rostral part attracts axonal growth cones and neural crest cells, whereas the caudal part is repulsive (see Figure 52–1). In the head such patterning is lacking as the cranial mesoderm is not segmented into somites but rather develops under the influence of the rhombomeres.

Neuronal Ensembles in the Brain Stem Reticular Formation Coordinate Reflexes and Simple Behaviors Necessary for Homeostasis and Survival

A variety of reflexes and simple behaviors are mediated by the cranial nerves. These range from simple autonomic and motor responses to more complex patterns of facial expression and more complex behaviors such as breathing and eating, which in turn come under voluntary control by the forebrain. The stereotypic motor responses that make up these behaviors are controlled by neurons in the brain stem reticular formation. Impairment of cranial nerve reflexes and motor patterns in patients with neurological disease can be used to identify the precise site of brain stem damage.

Cranial Nerve Reflexes Involve Mono- and Polysynaptic Brain Stem Relays

The response of the pupils to light (pupillary light reflexes) are determined by the balance between sympathetic tone in the pupillodilator muscles and parasympathetic tone in the pupilloconstrictor muscles of the iris. Sympathetic tone is maintained by postganglionic neurons in the superior cervical ganglion, which in turn are innervated by preganglionic neurons in the first and second thoracic spinal segments. Parasympathetic tone is supplied by postganglionic ciliary ganglion cells under the control of preganglionic neurons in the Edinger-Westphal nucleus and adjacent areas of the midbrain.

Light impinging on the retina activates a special class of retinal ganglion cells that act as brightness detectors. These ganglion cells receive inputs from rhodopsin-containing rods and cones, but also have their own photopigment, melanopsin, which allows them to respond to light even in patients who have degeneration of the rods and cones. These cells send their axons through the optic nerve, chiasm, and tract, bypassing the lateral geniculate nucleus to the olivary pretectal nucleus, where they synapse onto neurons whose axons travel through the posterior commissure to contact the preganglionic neurons in the Edinger-Westphal nucleus (Figure 45–7). Thus injury to the

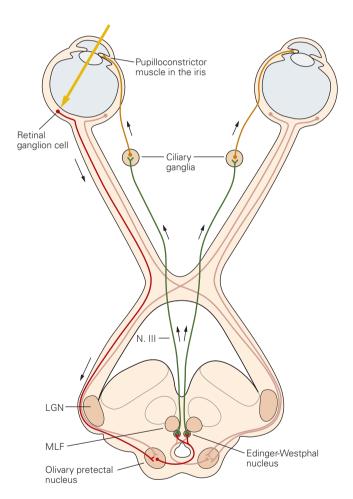

Figure 45–7 The pupillary response to light is mediated by the parasympathetic innervation of the iris. Retinal ganglion cells acting as luminance detectors send their axons through the optic tract to the olivary pretectal nucleus, at the junction of the midbrain and the thalamus. Neurons in this nucleus project through the posterior commissure to parasympathetic preganglionic neurons in and around the Edinger-Westphal nucleus. The axons of the preganglionic cells exit with the oculomotor (III) nerve and contact the ciliary ganglion cells, which control the pupilloconstrictor muscle in the iris. (LGN, lateral geniculate nucleus; MLF, medial longitudinal fasciculus.)

dorsal midbrain in the region of the posterior commissure can prevent pupillary light responses (midposition, fixed pupils), whereas injury to the oculomotor nerve eliminates parasympathetic tone to that pupil (fixed and dilated pupil). The melanopsin-containing retinal ganglion cells also project to the suprachiasmatic nucleus of the hypothalamus, where they entrain circadian rhythms to the day-night cycle.

Vestibulo-ocular reflexes stabilize the image on the retina during head movement by rotating the eyeballs counter to the direction of rotation of the head. These reflexes are activated by pathways from the vestibular ganglion and nerve to the medial, superior, and lateral vestibular nuclei, and from there to neurons in the reticular formation and ocular motor nuclei that coordinate eye movements. The reflex movements are seen most clearly in comatose patients, in whom turning the head will elicit counter-rotational movements of the eyes (so-called doll's eye movements). Damage to these pathways in the pons impairs these movements.

The *corneal reflex* involves closure of both eyelids as well as upward turning of the eyes (Bell's phenomenon) when the cornea is gently stimulated (eg, with a wisp of cotton). The sensory axons from the first division of the trigeminal nerve terminate in the spinal trigeminal nucleus, which relays the sensory signals to pattern generator neurons in the reticular formation adjacent to the facial motor nucleus. The pattern generator neurons provide bilateral inputs to the motor neurons that innervate the orbicularis oculi, which controls eye closure, and to the oculomotor nuclei, causing the elevation of the eyes. Because the output of the pattern generator is bilateral, damage along the sensory pathway prevents the reflex in both eyes, whereas damage to the facial nerve prevents closure on the same side only.

The *stapedial reflex* contracts the stapedius muscle in response to a loud sound, thus damping movement of the ossicles. The sensory pathway is through the cochlear nerve and nucleus to the reticular formation adjacent to the facial motor nucleus, and from there to the stapedial motor neurons, which run in the facial nerve. In patients with injury to the facial nerve (eg, Bell's palsy) the stapedial reflex is impaired, and the patient complains that sounds in that ear have a "booming" quality (hyperacusis).

A variety of gastrointestinal reflexes are controlled by multisynaptic brain stem relays. For example, the taste of food causes neurons in the solitary nucleus that project to the reticular formation adjacent to the nerve VII and IX nuclei to stimulate the preganglionic salivary neurons. The taste of food can also elicit gastric contractions and acid secretion, presumably through inputs from the solitary nucleus directly to parasympathetic preganglionic gastric neurons in the dorsal motor vagal nucleus.

The *gag reflex* protects the airway in response to stimulation of the posterior oropharynx. The afferent sensory fibers in the glossopharyngeal and vagus nerves terminate in the spinal trigeminal nucleus, whose axons project to the reticular formation adjacent to the nucleus ambiguus. Branchial motor neurons in the nucleus ambiguus innervate the posterior pharyngeal muscles, resulting in elevation of the palate, constriction of pharyngeal muscles (to expel the offending stimulus), and closure of the airway. Loss of the gag reflex on one side of the throat indicates injury to the medulla or to cranial nerves IX and X on that side.

Pattern Generator Neurons Coordinate Stereotypic and Autonomic Behaviors

Reflex responses such as the corneal or gag reflex are mediated by complex spatial and temporal patterns of activity in multiple motor nuclei. These patterns of activity are coordinated by *pattern generator neurons* in the adjacent reticular formation. Similar mechanisms control a variety of simple, stereotypic behaviors. For example, pools of pattern generator neurons in the reticular formation adjacent to the facial nucleus control facial expressions through stereotypic patterns of contraction of facial muscles simultaneously on the two sides of the face.

The patterns are so characteristic that Charles Darwin in his book on *Expression of the Emotions in Man and Animals* claimed that he could identify emotional states in animals like dogs and monkeys on the basis of contraction of homologous groups of facial muscles. Pattern generator neurons on each side of the brain stem project to the facial motor neurons on both sides of the brain, so that spontaneous facial expressions are virtually always symmetric. Even patients who have had major strokes in the cerebral hemispheres and cannot voluntarily move the contralateral orofacial muscles still tend to smile symmetrically when they hear a joke and can raise their eyebrows symmetrically.

Many orofacial movements involved in eating are produced by pattern generator neurons in the reticular formation near the cranial motor nuclei that mediate the behaviors. Licking movements are organized in the reticular formation near the hypoglossal nucleus, chewing movements near the trigeminal motor nucleus, sucking movements near the facial nucleus, and swallowing near the nucleus ambiguus. Not surprisingly, neurons in these reticular areas are closely interconnected with each other and receive inputs

from the part of the nucleus of the solitary tract concerned with taste and the part of the spinal trigeminal nucleus concerned with tongue and oral sensation.

A variety of responses organized by the brain stem require coordination of cranial motor patterns with autonomic and sometimes endocrine responses. A good example is the baroreceptor reflex, which insures an adequate blood flow to the brain (see Chapter 47). The nucleus of the solitary tract receives information about stretch of the aortic arch through the vagus (X) nerve and stretch of the carotid sinus through the glossopharyngeal (IX) nerve. This information is relayed to neurons in the ventrolateral medulla that produce a coordinated response that protects the brain against a fall in blood pressure.

Reduced stretch of the aortic arch and carotid sinus reduces drive to the parasympathetic preganglionic cardiac-vagal neurons in the nucleus ambiguus, resulting in reduced vagal tone and increased heart rate. Simultaneously, increased firing of neurons in the rostral ventrolateral medulla drives sympathetic preganglionic vasoconstrictor and cardioaccelerator neurons. This combination of increased cardiac output and increased vascular resistance elevates blood pressure. Meanwhile, other neurons in the ventrolateral medulla increase the firing of hypothalamic neurons that secrete vasopressin from their terminals in the posterior pituitary gland. Vasopressin also has a direct vasoconstrictor effect, and it maintains blood volume by reducing water excretion through the kidney.

Vomiting is another example of a coordinated response mediated by pattern generator neurons. Toxic substances that enter the blood stream can be detected by nerve cells in the area postrema, a small region adjacent to the nucleus of the solitary tract along the floor of the fourth ventricle. Unlike most of the brain, which is protected by a blood-brain barrier (see Appendix D), the area postrema contains fenestrated capillaries that allow its neurons to sample the contents of the blood stream. When these neurons detect a toxin, they activate a pool of neurons in the ventrolateral medulla that control a pattern of responses that clears the digestive tract of any poisonous substances. These responses include reversal of peristalsis in the stomach and esophagus, increased abdominal muscle contraction, and activation of the same motor patterns used in the gag reflex to clear the oropharynx of unwanted material.

A Complex Pattern Generator Regulates Breathing

One of the most important functions of the brain stem is control of breathing. The brain stem automatically generates breathing movements beginning in utero at 11 to 13 weeks of gestation in humans, and continues nonstop from birth until death. This behavior does not require any conscious effort, and in fact it is rare for us to even think about the need to breathe. The primary purpose of breathing is to ventilate the lungs to control blood levels of oxygen, carbon dioxide, and hydrogen ions (pH), normal levels of which are essential for survival. (These are often measured together clinically and referred to as "blood gases.") Breathing movements involve contraction of the diaphragm, which is achieved by activating the phrenic nerve. The diaphragm is assisted when necessary by accessory muscles of respiration, including the intercostal muscles, pharyngeal muscles (to change airway diameter), some neck muscles (which help expand the chest), the tongue protruder muscles (to open the airway), and even some facial muscles (which flare the nares).

Respiratory activity can be generated by the medulla even when it is isolated from the rest of the nervous system. Within the medulla many neurons have patterns of firing that correlate with inspiration or expiration (Figure 45–8A). Some neurons have more complicated patterns, such as firing only during early inspiration or late inspiration. These respiratory neurons are concentrated in two regions. The dorsal respiratory group, located bilaterally in and around the ventrolateral part of the nucleus of the solitary tract, receives respiratory sensory input, including afferents from stretch receptors in the lungs and peripheral chemoreceptors. Neurons in the dorsal respiratory group contribute to reflexes such as limitation of lung inflation at high volume (the Hering-Breuer reflex) and the response to low oxygen (hypoxia). The ventral respiratory group, a column of neurons in and around the nucleus ambiguus, coordinates respiratory motor output. Some of these neurons are motor neurons with axons that leave the brain through the vagus nerve and innervate accessory muscles of respiration.

Respiratory neurons within the medulla in the rostral part of the ventral respiratory group, in an area called the *pre-Bötzinger complex*, are important components in the network that generates the respiratory rhythm. When transverse brain slices are prepared from the rostral medulla, neurons in the pre-Bötzinger complex are able independently to generate a respiratory rhythm that can be recorded in the XII cranial nerve rootlets that emerge from the ventral surface of the slices (Figure 45–8B). When neurons in this cell group are selectively killed acutely in intact animals, the animals are unable to maintain a normal respiratory rhythm. However, other areas of the medulla, such as the parafacial respiratory group, also contribute to

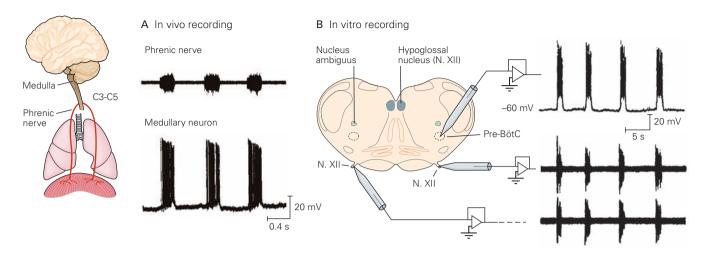

Figure 45–8 Rhythmic breathing is generated within the medulla.

A. Rhythmic motor activity in the phrenic nerve of a guinea pig is phase-locked to bursts of firing by neurons in the medulla. Each burst of firing in the phrenic nerve causes contraction of the diaphragm. Activity in the medullary neuron was recorded intracellularly. Neurons like this one project to the phrenic motor nucleus and contribute to the pattern of respiratory movement. (Reproduced, with permission, from Richerson and Getting 1987.)

B. Similar rhythmic firing can be recorded in vitro from accessory respiratory nerves, such as the hypoglossal (XII) nerve. The minimal tissue necessary to support this rhythm is a slice about 0.5 mm thick at the level of the rostral medulla. Neurons in the pre-Bötzinger complex (pre-BötC) near the nucleus ambiguus fire bursts that are phase-locked to the motor rhythm. Lesions of the pre-Bötzinger complex in vivo disrupt the normal respiratory rhythm, suggesting that its neurons are critical for producing the normal ventilatory motor pattern. (Reproduced, with permission, from Smith et al. 1991.)

respiratory rhythm generation. The exact roles of each of these areas, and their contributions to normal breathing, remain an active area of investigation.

The most important input into the respiratory pattern generator comes from chemoreceptors that sense oxygen (O₂) and carbon dioxide (CO₂). Under normal conditions ventilation is primarily regulated by the levels of CO₂ rather than O₂ (Figure 45–9A). However, breathing is strongly stimulated if O₂ becomes sufficiently low, such as at high altitude or in people with lung disease. The peripheral chemoreceptors in the carotid and aortic bodies respond primarily to a decrease in blood oxygen. During hypoxia they also respond to the increased acidity that results from an increase in CO₂ (water and CO₂ combine to form bicarbonate and hydrogen ions). Afferent fibers from peripheral chemoreceptors travel in the glossopharyngeal and vagus nerves and contact neurons in the dorsal respiratory group.

Central chemoreceptors in the brain stem respond to the decrease in pH induced by an increase in CO₂ (hypercapnia) but do not respond to hypoxia. Breathing increases when acidic solution is applied to the ventral surface of the medulla lateral to the pyramidal tract. Within this region and within the midline raphe

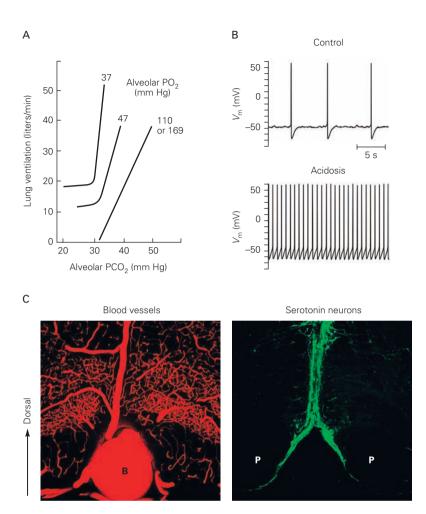

nuclei are serotonergic neurons that are sensitive to acidosis (Figure 45–9B). Because these neurons surround large arteries (Figure 45–9C) and project to respiratory neurons, they are thought to be central chemoreceptors that sense hypercapnia in the blood. Indeed, genetic deletion or silencing of all central serotonergic neurons in mice reduces the ventilatory response to hypercapnia by 50%. Glutamatergic neurons in the nearby retrotrapezoid nucleus of the rostral ventrolateral medulla, as well as in other areas of the brain stem, are also central chemoreceptors, and current work is aimed at determining the relative importance of each of these chemoreceptor pools to the overall ventilatory response to hypercapnia.

Breathing must be coordinated with many motor actions that share the same muscles. To accomplish this coordination, respiratory neurons in the medulla receive input from neuronal networks concerned with vocalization, swallowing, sniffing, vomiting, and pain. For example, the ventral respiratory group is connected with a part of the parabrachial complex in the pons termed the *pontine respiratory group* or *pneumotaxic center*. These pontine neurons coordinate breathing with behaviors such as chewing and swallowing. They can cause holding of the breath at full inspiration (called

Figure 45–9 Respiratory motor output is regulated by carbon dioxide in the blood.

A. Lung ventilation (determined by the rate and depth of breathing) in humans is steeply dependent on the partial pressure of carbon dioxide (PCO₂) at normal levels of the partial pressure of oxygen (PO₂) (> 100 mmHg). When PO₂ drops to very low values (< 50 mmHg) breathing is stimulated directly and also becomes more sensitive to an increase in PCO₂ (seen here as an increase in the slope of the curves for alveolar PO₂ of 37 and 47 mmHg). (Reproduced, with permission, from Nielsen and Smith 1952.)

- B. Central chemoreceptors in the medulla control ventilatory motor output to maintain normal blood CO₂. Serotonergic neurons within the raphe nuclei of the medulla may play this role by increasing the firing rate of the motor neurons when pH decreases (because of an increase in PCO₂). The records shown here are from in vitro recordings of a neuron in the raphe nuclei of a rat at two different levels of pH (7.4, control, and 7.2, acidosis). (Reproduced, with permission, from Wang et al. 2002.)
- C. Serotonergic neurons are closely associated with large arteries in the ventral medulla where they can monitor local changes in PCO₂. Two images of the same transverse section of the rat medulla show blood vessels after injection of a fluorescent dye into the arterial system (left) and antibody staining for tryptophan hydroxylase, the enzyme that synthesizes serotonin (right). The basilar artery (B) is on the ventral surface of the medulla between the pyramidal tracts (P). (Reproduced, with permission, from Bradley et al. 2002.)

apneusis) during eating and drinking. The reserve of air in the lungs permits a cough, if necessary, to expel any food or drink that may enter the airway. Other neurons in the intertrigeminal zone, between the motor and principal sensory trigeminal nuclei, receive facial and upper airway sensory fibers and project to the ventrolateral medulla to temporarily stop breathing to protect against accidental inspiration of dust or water.

The motor pattern generated by the respiratory centers is remarkably stable in normal people, but a variety of abnormal patterns can emerge under some conditions (eg, during disease). One of the most easily recognized is the Cheyne-Stokes respiratory pattern, which is characterized by repeated cycles of gradually increasing then decreasing ventilation, alternating with cessation of breathing (apnea). At the peak of each cycle a high CO_2 level at the central chemoreceptors causes hyperventilation. The hyperventilation

leads to a decrease in CO₂ in the capillaries of the lung, but it takes several breaths before this blood reaches the central chemoreceptors. By this time the subject has overcompensated, so that the CO₂ in the pulmonary capillaries is now too low. When that blood finally reaches the chemoreceptors, the low CO₂ causes apnea (Figure 45–10). This in turn causes an increase in CO₂ in the lung capillaries, and when this blood reaches the chemoreceptors it initiates another cycle.

Cheyne-Stokes breathing can be seen in patients with congestive heart failure in whom a decrease in cardiac output causes an increase in the delay between gas exchange in the lungs and the change in CO₂ at the central chemoreceptors in the brain stem. It is commonly seen in hospitalized patients. Although not dangerous in itself, it can indicate that there is a serious underlying cardiorespiratory problem that needs to be corrected. In normal healthy individuals this

cycle does not occur because it is suppressed by other sensory afferents to the ventral respiratory group.

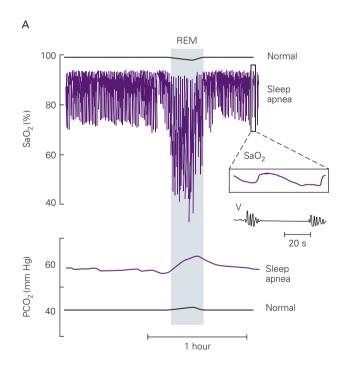

Conversely, at altitudes greater than 10,000 feet even normal individuals experience Cheyne-Stokes breathing, particularly during sleep, probably because the relative hypoxia sensitizes the $\mathrm{CO_2}$ receptors. A variety of other symptoms (headaches, insomnia, breathlessness, nausea) also result from the hypoxia at high altitude. Many of these symptoms can be prevented by taking acetazolamide, which causes a decrease in brain pH. The decrease in pH stimulates central chemoreceptors, which increase ventilation and maintain blood $\mathrm{O_2}$ levels closer to normal. When severe, the best treatment is to breathe oxygen or to return to lower altitude.

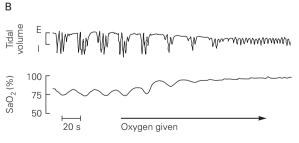

A variety of descending inputs can influence the brain stem respiratory system. Voluntary motor pathways can take over the control of breathing during talking, eating, swimming, or playing a musical instrument. Descending inputs cause hyperventilation at the onset of exercise, in anticipation of an increase in oxygen demand. In fact, this leads to a sustained drop in blood CO₂ during exercise—the opposite of what would be expected for a negative feedback control system. Other descending inputs from the limbic system produce hyperventilation in connection with pain or anxiety, and in some people may be responsible for causing spontaneous panic attacks, characterized by hyperventilation and a feeling of suffocation. These various descending inputs allow seamless integration of breathing with other brain functions, but they are superseded by the need to maintain blood gas homeostasis, as even a small increase in CO₂ produces severe air hunger or dyspnea. Thus the respiratory control system is a fascinating example of a brain stem pattern generator that must be sufficiently stable to insure survival yet flexible enough to accommodate a wide variety of behaviors.

Figure 45-10 Breathing may become unstable during sleep.

A. Sleep apnea (cessation of breathing) is a common problem that often goes undetected. The records here show blood oxygen saturation (SaO₂) and CO₂ partial pressure (PCO₂) during sleep in a normal person (black trace) and a patient with obstructive sleep apnea (purple traces). In the normal person SaO₂ remains near 100%, and (PCO₂) remains near 40 mmHg during both rapid eye movement (REM) and non-REM sleep. In the patient with sleep apnea, reduced muscle tone during sleep allows collapse of the upper airway, resulting in obstruction and apnea. The repetitive attacks of apnea at the rate of approximately one per minute cause the patient's SaO₂ to fall repetitively and dramatically. (The inset shows a period of approximately 80 seconds on an expanded scale. Ventilation (V) begins at the nadir of the SaO₂ and again ceases when the blood oxygen increases.) During non-REM sleep the patient's PCO₂ increases to near 60 mm Hg. During REM sleep the SaO₂ and PCO₂ become even more abnormal, as worsening airway hypotonia causes greater obstruction. Many people with sleep apnea wake up repeatedly during the night because of the apnea, but the arousals are too brief for them to be aware that their sleep is interrupted. (Modified, with permission, from Grunstein and Sullivan 1990.)

B. Breathing becomes unstable during sleep at high altitudes in most normal individuals. The upper trace shows an example of a Cheyne-Stokes breathing pattern in a healthy person, during the first night after arriving at an altitude of 17,700 feet, where the low partial pressure of oxygen in the air reduces the blood $\rm SaO_2$ to approximately 75 to 80%. Repeated cycles of waxing and waning ventilation are separated by periods of apnea. Administration of supplemental oxygen results in a rapid return to a normal respiratory pattern. This abnormal pattern disappears in most people after they have acclimated to the altitude. (Reproduced, with permission, from Lahiri et al. 1984.)

An Overall View

The plan for the brain stem and the cranial nerves unfolds early in development, as neurons assemble into clusters that come, in time, to assume their functional organization. Building on the basic plan of the spinal cord, motor and sensory neurons concerned with the face, head, neck and internal viscera form into discrete nuclei with specific functions and territories of innervation.

Neurons in the reticular formation surrounding these cranial nerve nuclei develop into ensembles of neurons that can generate patterns of autonomic and motor response that subserve simple, stereotyped, coordinated functions ranging from facial expression to feeding and breathing. These behavior patterns are sufficiently complex and flexible to represent the entire behavioral repertory of a newborn baby. As the forebrain develops and exerts its control over these brain stem pattern generators, a variety of more complex responses and ultimately volitional control of behavior evolves.

Even a skilled actor, however, finds it difficult to produce the facial expressions associated with specific emotions unless he recreates the emotional states internally, thereby triggering the pre-patterned facial expressions associated with those feeling states. Thus, some of the most complex human emotions and behaviors are played out unconsciously by means of stereotypic patterns of motor and autonomic responses in the brain stem.

An Overall View

Postscript: Evaluation of the Comatose Patient

s we learned in the previous Chapter, the brain stem can respond independently to the environment with stereotypic actions. We have also seen, in discussing the sensory and motor systems, that the brain stem is the conduit for all ascending and descending pathways between the forebrain, spinal cord, and peripheral nervous system. In this chapter we examine still a third role of the brain stem, as the modulatory center that orchestrates the activity of the rest of the central nervous system, ensuring that its activity is optimized.

This modulatory function is mediated by several small groups of neurons in the brain stem. These neurons project widely, using as neurotransmitters acetylcholine and the monoamines (norepinephrine, epinephrine, serotonin, dopamine, and histamine). Many of the monoaminergic groups modify pain and help regulate the autonomic nervous system to maintain internal homeostasis. Some are essential for controlling the level of behavioral arousal; and together they influence attention, mood, and memory. Because they are involved in the pathophysiology of many human diseases and are targets of many commonly used drugs, these monoaminergic and cholinergic neurons are also important for clinical care.

Behaviors we regard as uniquely human, such as memory, language, and compassion, depend heavily on modulation of forebrain function by the ascending cholinergic and monoaminergic systems. This dependence is seen clinically in the links between Alzheimer's disease and the acetylcholine system, schizophrenia and the dopaminergic system, and alleviation of depression with drugs that affect serotonergic and noradrenergic synapses. Thus, although the brain stem is phylogenetically primitive, the modulatory systems that project from this region enable and modulate many of the higher-order behaviors that we regard as most human.

Ascending Monoaminergic and Cholinergic Projections from the Brain Stem Maintain Arousal

Some neurons in the brain stem that project to the forebrain control wakefulness and sleep. In the mid-1930s

Frederic Bremer found that transection of the cat's brain stem at the midbrain level produced a continuous sleep-like state, whereas transections that separated the medulla from the spinal cord did not (Figure 46–1). These experiments demonstrate that the portion of the brain stem from the midbrain to the medulla keeps the forebrain awake.

Consistent with this view, experiments in 1949 by Guiseppi Moruzzi and Horace Magoun found that damage to the brain stem reticular formation in cats led to loss of wakefulness. Conversely, stimulating the reticular formation immediately converted the electroencephalogram (EEG) of a sleeping cat to a waking EEG. Transection of the brain stem at the level of the midpons or lower did not cause loss of wakefulness, indicating that the critical structures that need to be connected to the forebrain for wakefulness are located in the rostral pons and caudal midbrain.

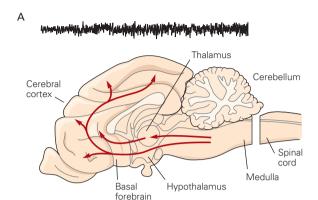

Moruzzi and Magoun proposed that this part of the brain stem provides a general activation energy for the entire brain and therefore called it the reticular activating system. Today this system is more accurately called the ascending arousal system, because we know it is not confined to the reticular formation. As we shall learn in Chapter 51, sleep and waking are regulated by interactions between this ascending arousal system and sleep-promoting regions in other parts of the brain. Damage to the ascending arousal system or its projections in the thalamus and hypothalamus leads to coma

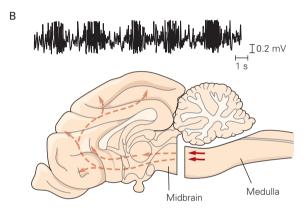

Figure 46–1 Ascending projections from the rostral brain stem are necessary for maintaining arousal of the cortex.

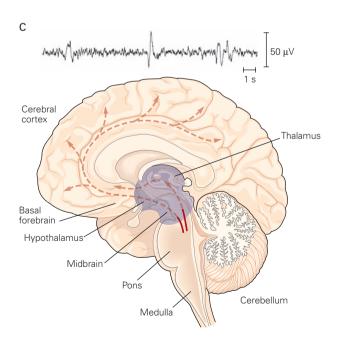

A. Transection of the brain stem in the lower medulla of a cat causes low-amplitude, fast electroencephalogram (EEG) activity characteristic of wakefulness. Animals appear awake and respond to sensory input from cranial nerves, but the muscles innervated by the spinal cord, including the diaphragm (which is required for breathing), are paralyzed.

B. Transection of the brain stem of a cat between the superior and inferior colliculi in the midbrain causes a sleep-like state from which the animal cannot be aroused. The EEG shows periods of slow delta waves (1–3 Hz) alternating with spindles (bursts of 8–11 Hz activity that wax and wane over a few seconds and are generated by the intact thalamus).

C. In humans injury to the rostral pons, the midbrain, or the thalamus and hypothalamus (shaded areas) causes impairment of consciousness. As shown here, the EEG of a drowsy patient consists of theta activity (4–7 Hz waves) and some larger delta waves. As the patient becomes less arousable, the amount of delta activity increases. Spindles similar to the cat appear as humans enter slow wave sleep but may not occur in coma if the thalamus is impaired.

(Figure 46–1C, and see the postscript, "Evaluation of the Comatose Patient," at the end of this chapter).

The ascending arousal system was originally viewed as a heterogeneous collection of neurons distributed diffusely throughout the brain stem reticular formation, which had widespread projections. This view changed radically in the early 1960s when Nils-Åke Hillarp and his students in Sweden used histofluorescence to discover that the neurons in this brain stem system fall into chemically distinct groups based on their monoamine neurotransmitter content. In a brilliant series of histochemical experiments they defined the location and projections of these neurons based on differences in the fluorescence signals produced by the different monoamines: norepinephrine, dopamine, and serotonin (Figure 46–2).

These findings were later expanded in studies that used antibodies against the synthetic enzymes for the monoamine neurotransmitters (which also allowed visualization of histamine and epinephrine) and acetylcholine. The connectivity of these cell groups is remarkable. Whereas most nuclei in the central nervous system project to specific regions or to a limited set of nuclei, the monoaminergic and cholinergic neurons of the ascending arousal system have widespread projections, some to virtually every part of the central nervous system.

A major part of the ascending arousal system consists of monoaminergic and cholinergic neurons in the brain stem. These neurons are found primarily in four regions (Figure 46–3A):

- 1. The locus ceruleus, which contains noradrenergic neurons
- 2. The dorsal and median raphe nuclei, which contain primarily serotonergic, but also some dopaminergic neurons
- 3. The pedunculopontine and laterodorsal tegmental nuclei, which contain cholinergic neurons
- 4. The tuberomammillary nucleus, which contains histaminergic neurons

The monoaminergic pathways from the locus ceruleus, and dorsal and median raphe nuclei, are thought to regulate sleep and waking. Other neurons in the parabrachial nucleus in the rostral pons and caudal midbrain, which largely use glutamate as a neurotransmitter, are also thought to contribute to the regulation of wakefulness and sleep. In addition to these reticular neurons, neurons in the lateral hypothalamus that contain the peptide neurotransmitters orexin and melanin-concentrating hormone are important for sleep and waking. Finally, cholinergic and GABA-ergic (γ -aminobutyric acid)

neurons in the basal forebrain contribute to arousal through diffuse cortical projections.

Stimulation of noradrenergic neurons in the locus ceruleus or histaminergic cells in the tuberomammillary nucleus causes increases in EEG arousal (Figure 46–3B), indicating that these systems play an important role in cortical and behavioral arousal. However, lesions restricted to one biogenic amine cell group do not cause profound loss of wakefulness, suggesting that the various cell groups probably have overlapping and at least partly redundant roles in sleep/wake regulation. As we will see, the monoaminergic pathways alter specific cellular properties of postsynaptic neurons in the thalamus and cerebral cortex, enhancing alertness and interaction with environmental stimuli.

At the junction of the midbrain and diencephalon the projections from the ascending arousal system split into two major branches, dorsal and ventral. The dorsal branch terminates in the thalamus. The ventral branch travels through the lateral hypothalamic area and is joined by ascending projections from the hypothalamus and the basal forebrain before terminating throughout the cerebral cortex. Lesions that disrupt either of these two branches impair consciousness.

Monoaminergic and Cholinergic Neurons Share Many Properties and Functions

Monoamines are biochemical compounds with an aromatic ring that are synthesized from aromatic amino acids. They include the catecholamines (epinephrine, norepinephrine, and dopamine), serotonin, and histamine. Neurons that use monamines as neurotransmitters share many cellular properties. For example, most continue to fire spontaneous action potentials in a highly regular pattern when isolated from their synaptic inputs in brain slice preparations. Their action potentials typically are followed by a slow membrane depolarization that leads to the next spike (Figure 46–4A).

The spontaneous regular firing pattern of monoaminergic neurons is regulated by intrinsic pacemaker currents. Tonic firing in vivo may be important for ensuring the continuous delivery of monoamines to targets. For example, the basal ganglia depend on continuous exposure to dopamine from the neurons of the substantia nigra to facilitate motor responses.

The properties of monoaminergic neurons are suited to their unique and widespread modulatory roles in brain function. Indeed, some axon terminals of monoaminergic cells do not even form conventional synaptic connections, instead releasing neurotransmitter diffusely to many targets at once (Figure 46–4B).

Most monoamine neurotransmission occurs by means of metabotropic synaptic actions through G protein-coupled receptors. Many monoaminergic neurons corelease neuropeptides, which have slow effects through other G protein-coupled receptors. Thus, although some monoamine responses are mediated through fast synaptic mechanisms (see Chapter 10), many involve slower metabotropic and neuromodulatory actions as well (see Chapter 11).

Some cholinergic neurons in the brain stem share certain of these properties. For example, cholinergic neurons in the pedunculopontine and laterodorsal tegmental nuclei have widespread projections, providing the bulk of the cholinergic input to the thalamus, particularly to its relay and reticular nuclei. Many effects of cholinergic neurons also are mediated by G protein-coupled muscarinic receptors.

Many Monoaminergic and Cholinergic Neurons Are Linked to the Sleep-Wake Cycle

Most central neurons fire maximally during waking, decrease firing in a phase of sleep called slow-wave sleep, and then increase firing again during a phase of sleep called rapid eye movement (REM) sleep, the phase of the sleep cycle in which dreams are particularly likely to occur (see Chapter 51). Motor neurons are an exception; they have their lowest firing frequency during REM sleep because they are actively inhibited to prevent the acting out of dreams.

Noradrenergic, serotonergic, and histaminergic neurons are unlike most central neurons and more like motor neurons. They are maximally active during waking, their firing rates progressively decrease with increasing depth of non-REM sleep, and they stop almost completely during REM sleep (Figure 46–4A). Dopaminergic neurons within the dorsal raphe region also are most active during waking, but it has not yet been possible to distinguish their activity patterns during non-REM and REM sleep from those of the serotonergic neurons with which they intermingle.

In contrast to monoaminergic neurons, the firing rates of cholinergic neurons in the pedunculopontine and laterodorsal tegmental nuclei decrease during non-REM sleep but increase during REM sleep (Figure 46–4A). These and other properties indicate that the role of acetylcholine in controlling arousal is different from that of the monoamines.

The sleep-wake cycle has a strong circadian rhythm. The pacemaker for this rhythm is the suprachiasmatic nucleus in the hypothalamus (see Chapter 51). The suprachiasmatic nucleus regulates the circadian rhythm of sleep and waking primarily through connections

with other hypothalamic areas, such as the dorsomedial nucleus. The dorsomedial nucleus in turn contacts both sleep- and wake-promoting cell groups in the hypothalamus and brain stem. As a result, the ascending arousal system entrains to the circadian rhythm (Figure 46–4A).

Monoaminergic and Cholinergic Neurons Maintain Arousal by Modulating Neurons in the Thalamus and Cortex

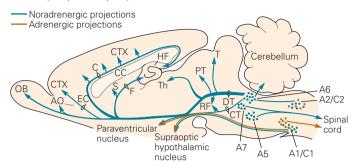

The monoaminergic and cholinergic neurons induce arousal by activating cortical neurons both directly and indirectly. They do this, in part, by modulating the activity of neurons in the hypothalamus, basal forebrain, and thalamus that activate the cerebral cortex.

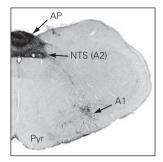

Ionic mechanisms produce different modes of firing in thalamic neurons during sleep and wakefulness; during sleep the neurons fire in bursts, and during wakefulness they fire single spikes (see Chapter 51). Thalamic relay neurons exhibit activity in vitro that is similar to that seen in the intact brain during slow-wave sleep. When these neurons in brain slices are depolarized by injection of current, their firing pattern converts from burst mode to single-spike mode (like waking activity). Similarly, the firing pattern of thalamic and cortical neurons in brain slices changes from burst mode to single-spike mode when the cells are depolarized following application of acetylcholine, norepinephrine, serotonin and histamine (Figure 46-5A). Thus these neurotransmitters of the ascending arousal system regulate cortical activity in part by altering the firing of thalamic neurons.

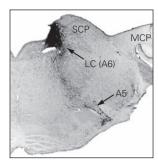

Many pharmacological agents that target monoamines and acetylcholine influence arousal. For example, antihistamines cause drowsiness, serotonin reuptake blockers decrease the amount of REM sleep, and nicotine is a powerful stimulant. In addition, arousal is induced by amphetamines, cocaine, and other drugs that block dopamine reuptake; mice lacking the dopamine transporter are insensitive to such drugs.

Patients with Parkinson disease, who lose dopaminergic neurons in the substantia nigra, also lose noradrenergic neurons in the ascending arousal system and tend to be abnormally sleepy during the day. Some drugs used to treat Parkinson disease activate the D_2 dopamine receptor on presynaptic terminals of the remaining dopaminergic arousal neurons, which results in presynaptic inhibition, thus reducing dopamine release. As a result, although these drugs may make the movement disorder better (through their effects on postsynaptic D_2 receptors on neurons in the striatum), the inhibitory effect on remaining dopaminergic cells in the arousal system may exacerbate daytime sleepiness.

A Norepinephrine/Epinephrine

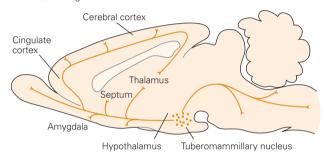

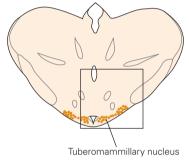

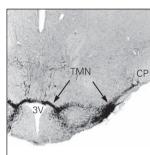

B Histamine

C Serotonin

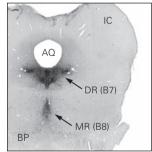

Figure 46–2 Locations and projections of monoaminergic and cholinergic neurons in the rat brain. (3V, third ventricle; AC, anterior commissure; AP, area postrema; AQ, Sylvian aqueduct; ARC, arcuate nucleus; BM, nucleus basalis of Meynert; BP, brachium pontis; CD, caudate; CP, cerebral peduncle; DBh, horizontal limb of the diagonal band; DR, dorsal raphe; FX, fornix; IC, inferior colliculus; LC, locus ceruleus; LDT, laterodorsal tegmental nucleus; MCP, middle cerebellar peduncle; MGN, medial geniculate nucleus; MR, median raphe; MS, medial septum; MTT, mammillothalamic tract; NTS, nucleus tractus solitarius; OC, optic chiasm; PPT, pedunculopontine tegmental nucleus; PUT, putamen; Pyr, pyramidal tract; RM, raphe magnus; SC, superior colliculus; SCP, superior cerebellar peduncle; SN, substantia nigra; STN, spinal trigeminal nucleus; TMN, tuberomammillary nucleus; VTA, ventral tegmental area.)

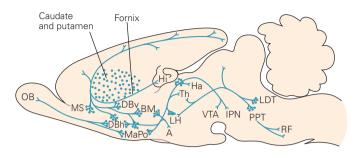

A. Noradrenergic neurons (A groups) and adrenergic neurons (C groups) are located in the medulla and pons (shaded). The A2 and C2 groups in the dorsal medulla are part of the nucleus of the solitary tract. The A1 and C1 groups in the ventral medulla are located near the nucleus ambiguus. Both groups project to the hypothalamus; some C1 neurons project to sympathetic

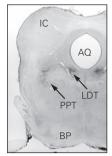

preganglionic neurons in the spinal cord and control cardiovascular and endocrine functions. The A5, A6 (locus ceruleus), and A7 cell groups in the pons project to the spinal cord and modulate autonomic reflexes and pain sensation. The locus ceruleus also projects rostrally to the forebrain and plays an important role in arousal and attention.

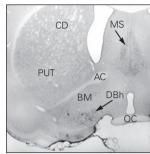

B. All histaminergic neurons are located in the posterior lateral hypothalamus, mostly within the tuberomammillary nucleus. These neurons project to virtually every part of the neuraxis and play a major role in arousal.

C. Serotonergic neurons (B groups) are found within the medulla, pons, and midbrain, mostly near the midline in the raphe nuclei. Those within the medulla (the B1–B4 groups corresponding to the raphe magnus, raphe obscurus, and raphe pallidus) project throughout the medulla and spinal cord and modulate afferent pain signals, thermoregulation, cardiovascular control, and breathing. Those within the pons and midbrain (the B5–B9 groups in the raphe pontis, median raphe, and dorsal raphe) project throughout the forebrain and contribute to arousal, mood, and cognition.

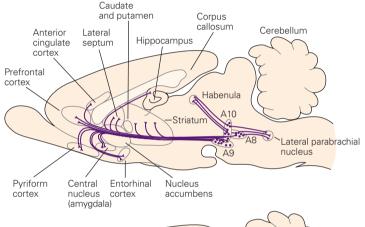

D Acetylcholine

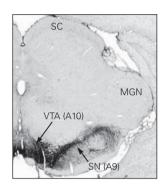

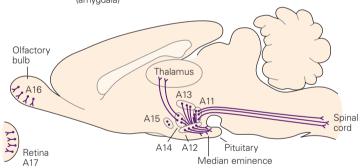

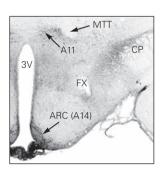

E Dopamine

- D. Cholinergic neurons (Ch groups) are located in the pons, midbrain, and basal forebrain. Those in the pons and midbrain (mesopontine groups) are divided into a ventrolateral cluster (pedunculopontine nucleus) and the dorsomedial cluster (laterodorsal tegmental nucleus). The mesopontine cholinergic neurons project to the brain stem reticular formation and the thalamus. Those in the basal forebrain are found in the medial septum, the nuclei of the vertical and horizontal limbs of the diagonal band, and the nucleus basalis of Meynert. These neurons project throughout the cerebral cortex, hippocampus, and amygdala. Both groups play an important role in arousal, and the basal forebrain groups are also involved in attention.
- E. Dopaminergic neurons are located in the midbrain and hypothalamus. The dopaminergic cell groups were originally included with the noradrenergic lettering system and are still labeled as A groups. The A9 cell group is located in the

substantia nigra pars compacta. The A8 group is in a region of the midbrain tegmentum, dorsally adjacent to the substantia nigra. These two groups of neurons project to the striatum and play an important role in initiation of movement. The A10 group is located in the ventral tegmental area just medial to the substantia nigra. These cells project to the frontal and temporal cortex and limbic structures of the basal forebrain and play a role in emotion and memory. The A11 and A13 cell groups in the zona incerta of the hypothalamus project to the lower brain stem and spinal cord and regulate sympathetic preganglionic neurons. The A12, A14, and A15 cell groups are components of the neuroendocrine system. Some of them inhibit release of prolactin into the hypophysial portal circulation, and others control gonadotrophin secretion. Dopaminergic neurons are also found in the olfactory bulb (A16) and the retina (A17).

Monoamines Regulate Many Brain Functions Other Than Arousal

In addition to their well-defined role in regulating arousal, monoaminergic neurons also regulate cognitive performance during waking and affect a variety of other central nervous system functions. We illustrate these effects with four examples.

Cognitive Performance Is Optimized by Ascending Projections from Monoaminergic Neurons

Although the monoamines and acetylcholine each induce arousal, they have different effects on cognitive function during waking. This occurs in part because each of the monoamines, and acetylcholine, uses distinct intracellular signaling pathways that act on different complements of ion channels (Figure 46–5B). Thus, in addition to differences in regional distribution, each type of monoamine receptor has a unique cellular and subcellular distribution (Figure 46–6). Hence each part of the brain and each type of neuron is affected differently by monoamines and acetylcholine.

Neurons of the locus ceruleus, which release norepinephrine, play an important role in attention. These neurons have a low baseline level of activity in drowsy monkeys. In alert monkeys the cells have two modes of activity that correspond to differences in behavior. In the *phasic mode* the baseline activity of the neurons is low to moderate. Just before the monkey responds to a stimulus to which it has been attentive, the cells are briefly excited. This pattern of activity correlates with and may facilitate selective attention. In contrast, in the tonic mode the baseline level of activity is elevated and does not change in response to external stimuli. This mode of firing may disrupt the ability to maintain attention on a single task and help to search for a new behavioral and attentional goal when the current task is no longer rewarding (Figure 46-7).

Monoaminergic inputs to the dorsolateral prefrontal cortex improve working memory (see Chapters 65 and 67). Microinjection of dopamine-receptor antagonists into the dorsolateral prefrontal cortex of monkeys markedly reduces the animals' ability to remember a location for several seconds. In functional magnetic resonance imaging (fMRI) studies of humans,

Figure 46–3 Major cell groups in the ascending arousal system in the rat brain.

A. Neurons using the neurotransmitters norepinephrine, serotonin, dopamine, histamine, and acetylcholine have widespread forebrain projections, but there are important differences in the distributions. They all contribute to arousal, but effects on other brain functions vary. Other groups of neurons that play an important role in arousal include the glutamatergic parabrachial nucleus and hypothalamic neurons that secrete orexin and melaninconcentrating hormone.

B. Stimulation of noradrenergic neurons in the locus ceruleus (LC) induces arousal. The cholinergic agonist bethanechol was microinjected directly into the locus ceruleus of a lightly anesthetized (halothane) rat. Arousal, which shows up in the EEG as low voltage, fast activity (arrow), coincides in time with the bethanechol-induced increase in firing of the locus ceruleus neurons. (EEG, electroencephalogram; ILT, intralaminar thalamic nuclei; RT, reticular nucleus of the thalamus.) (Reproduced, with permission, from Berridge and Foote 1991.)

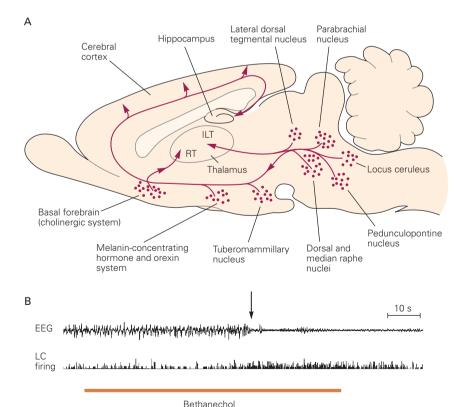

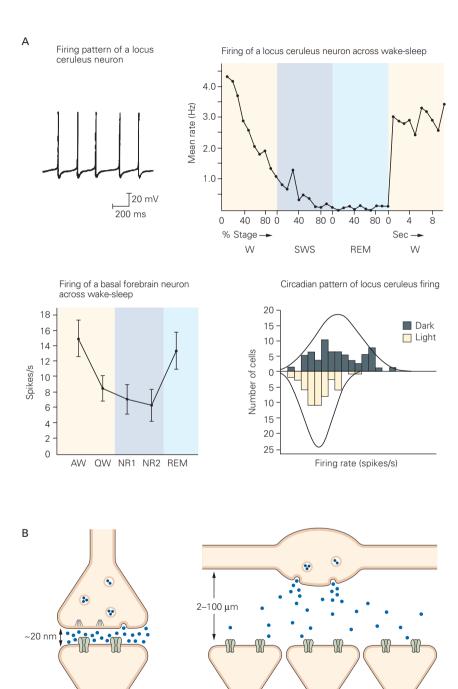

Figure 46–4 Monoaminergic neurons have common properties.

A. The baseline electrophysiological properties of all monoaminergic neurons are similar. The slow, regular firing pattern of a noradrenergic neuron in the locus ceruleus is shown at the upper left. Serotonergic and histaminergic neurons are similar. The upper right shows the average impulse activity of noradrenergic cells in the locus ceruleus in a behaving rat shown during different stages of sleep and waking. Histaminergic and serotonergic neurons exhibit a similar pattern of activity over the sleep-wake cycle. The bottom left shows the average activity of presumptive cholinergic neurons in the basal forebrain. Note decreased activity from waking to slow sleep (NR1 and NR2) but increased activity during REM sleep. The lower right shows that firing of neurons in the locus ceruleus follows a circadian rhythm. Histograms show the distributions of firing rates of the neurons during dark and light periods of the circadian cycle. Lesions of the dorsomedial nucleus of the hypothalamus eliminate the difference in locus ceruleus firing rates during the dark and light periods. (REM, rapid eye movement sleep; SWS, slow-wave sleep; W, wakefulness; AW, active wakefulness; QW, quiet wakefulness; NR1, lighter stages of non-REM sleep; NR2, deeper stages of non-REM sleep.) (Upper right reproduced, with permission, from Aston-Jones and Bloom 1981; lower left modified, with permission, from Szymusiak et al. 2000; lower right reproduced, with permission, from Aston-Jones et al. 2001.)

B. At conventional synapses the presynaptic terminal is closely aligned with the postsynaptic membrane (left). In contrast, the *en passant* terminal diffusely releases a transmitter that can affect several synapses within the immediate area (right). Acetylcholine and each of the monoamines can be released using this so-called paracrine mechanism.

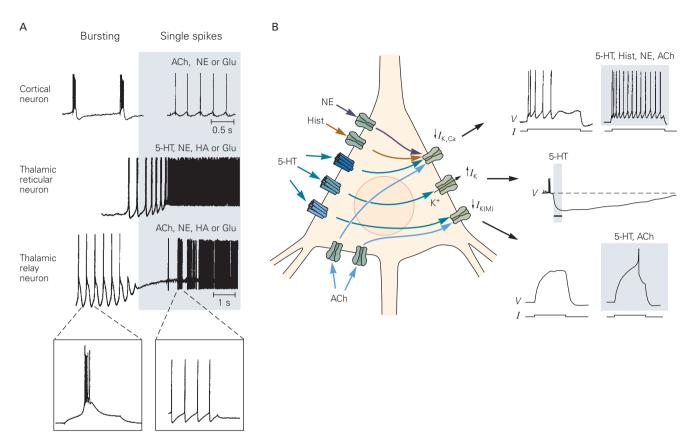

Figure 46–5 Monoaminergic and cholinergic systems induce and maintain arousal by modulating the activity of thalamic and cortical neurons.

A. The firing patterns of cortical and thalamic neurons are converted from burst mode to single-spike mode by the action of acetylcholine or monoamines. Recordings are from neurons in brain slices. (Reproduced, with permission, from Steriade, McCormick, and Sejnowski 1993.)

B. The effects of monoamines and acetylcholine on single neurons are complementary, not identical. In a cortical pyramidal neuron serotonin (5-HT) produces different effects on three different ion channels by acting on three types of receptors. Other monoamines and acetylcholine produce some but not all the responses observed with serotonin. The tops of the action potentials have been cut off in the middle and bottom traces. (Modified, with permission, from McCormick 1992.)

Top: Left trace. Depolarization elicits a train of action potentials that shows a gradual decrease in firing rate (spike accommodation) caused by entry of Ca²⁺ into the neuron during a burst of

action potentials turning on a calcium-activated K⁺ current, $I_{\rm K,Ca}$. **Top:** Right trace. Serotonin inhibits $I_{\rm K,Ca}$ and thus blocks spike accommodation, permitting the neuron to sustain firing during depolarization. The second-messenger pathways activated by histamine (acting on H2 receptors), norepinephrine (acting on β -adrenergic receptors), and acetylcholine (acting on muscarinic receptors) converge to also inhibit $I_{\rm K,Ca}$.

Middle: A different type of serotonin receptor activates a different K^+ current, causing sustained hyperpolarization and inhibition of firing.

Bottom: *Left trace.* A third type of serotonin receptor inhibits the M-type K^+ current. A small depolarizing pulse activates the M-type K^+ current, which prevents the neuron from firing. *Right trace.* When the M-type current is inhibited by serotonin or acetylcholine, a small depolarizing pulse is able to produce an action potential (right).

(5-HT, serotonin; ACh, acetylcholine; Glu, glutamate; Hist, histamine; HA, hydroxyapatite; NE, norepinephrine.)

 D_1 agonist drugs increased activation of the dorsolateral prefrontal cortex during a memory task. Injection of agonists of the α_2 -adrenergic receptor into the dorsolateral prefrontal cortex of aging monkeys can also improve performance on working memory tasks.

Dopamine also has been linked to reward-based learning. Rewards are objects or events for which an

animal will work (see Chapter 49) and are useful in reinforcing behavior. Activity of dopaminergic neurons increases when a reward (such as food or juice) is unexpectedly given. But after animals are trained to expect that a reward will follow a conditioned stimulus, the activity of the neurons increases immediately after the conditioned stimulus rather than after the reward.

A 5-HT_{1a} receptors

Figure 46–6 Different types of serotonin receptors are distributed differently within the brain. The left images are positron emission tomography (PET) scans showing the density of two types of serotonin (5-HT) receptors in the brain of a normal person, and the right images are magnetic resonance imaging (MRI) scans showing the anatomy at the same level.

A. The 5-HT_{1a} receptors are concentrated mainly in the medial temporal lobe (**red**), and less so in the neocortex (**blue**). (Modified, with permission, from Plenevaux et al. 2000.)

B. At the same level, 5-HT_{2a} receptors are concentrated mostly in the frontal and temporal neocortex and less so in the medial temporal lobe. (Modified, with permission, from Smith et al. 1998.)

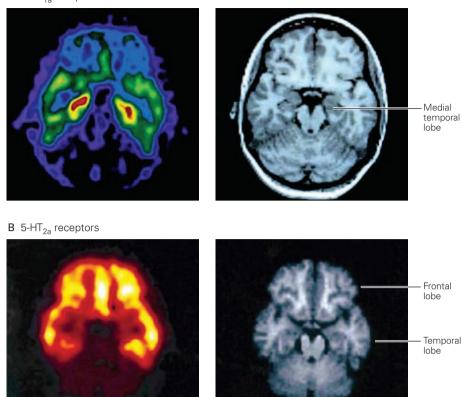

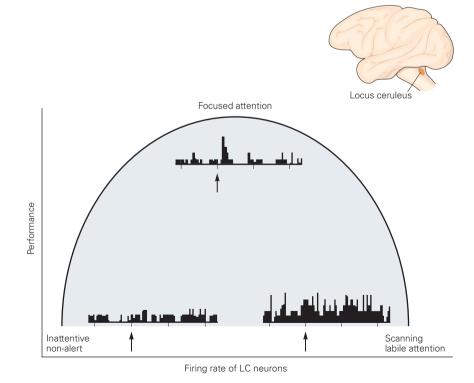

Figure 46-7 Locus ceruleus neurons exhibit different patterns of activity with different levels of attentiveness and task performance. Inverted U curve shows the relationship between a monkey's performance on a target detection task and the level of locus ceruleus (LC) activity. Histograms show the responses of LC neurons to presentation of the target during different levels of task performance. Performance is poor at low levels of LC activity because the animals are not alert. Performance is also poor when baseline activity is high because the higher baseline is incompatible with focusing on the assigned task. Performance is optimal when baseline activity is moderate and phasic activation follows presentation of the target (arrow). The tonic mode (with high baseline activity) might be optimal for tasks (or contexts) that require behavioral flexibility instead of focused attention. If so, the LC could regulate the balance between focused and flexible behavior. (Reproduced, with permission, from Aston-Jones and Cohen 2005.)

This pattern of activity indicates that dopaminergic neurons provide a reward-prediction error signal, an important element in reinforcement learning. The importance of dopamine in learning is also supported by observations that lesions of dopaminergic systems prevent reward-based learning. The same dopaminergic pathways that are important for reward and learning are involved in addiction to many drugs of abuse (see Chapter 49)

Monoamines Are Involved in Autonomic Regulation and Breathing

Neurons in the adrenergic C1 group in the rostral ventrolateral medulla play a key role in maintaining resting vascular tone as well as adjusting vasomotor tone necessitated by various behaviors. For example, an upright posture disinhibits neurons in the rostral ventrolateral medulla that directly innervate the sympathetic preganglionic vasomotor neurons, thus increasing vasomotor tone to prevent a drop in blood pressure (the baroreceptor reflex). Neurons in the noradrenergic A5 group in the pons inhibit the sympathetic preganglionic neurons and play a role in depressor reflexes (eg, the fall in blood pressure in response to deep pain).

Serotonin regulates many different autonomic functions including gastrointestinal peristalsis, thermoregulation, cardiovascular control, and breathing. Electrical stimulation of serotonergic neurons within the medullary raphe nuclei increases heart rate and blood pressure. Serotonergic neurons in the medulla also project to neurons in the medulla and spinal cord

that regulate breathing (Figure 46–8A), and stimulation of the medullary raphe nuclei increases respiratory motor output (see Chapter 45). Some serotonergic neurons in the medulla are central chemoreceptors (CO₂ sensors), firing faster in response to an increase in CO₂ and in turn stimulating breathing to restore arterial acid/base homeostasis. Serotonergic neurons in the midbrain also sense arterial CO₂ (Figure 46–8B). These neurons may induce arousal, anxiety, and changes in cerebral blood flow when blood CO₂ increases, responses which are important for survival when airflow is obstructed. Consistent with these ideas, genetic deletion of all serotonergic neurons in mice leads to a large decrease in the ventilatory response to breathing air with increased CO₂ (hypercapnia) and these mice no longer wake up when presented with the same stimulus while asleep.

The role of serotonergic neurons as CO₂ receptors may explain why defects in the serotonergic system have been linked to sudden infant death syndrome (SIDS). SIDS is the leading cause of postneonatal mortality in the Western world, responsible for six infant deaths every day in the United States. It was defined by an expert panel of pathologists and pediatricians as "the sudden and unexpected death of an infant under one year of age that remains unexplained after a complete clinical review, autopsy, and death scene investigation and occurs in seemingly healthy infants usually during a sleep period" (Figure 46–8C).

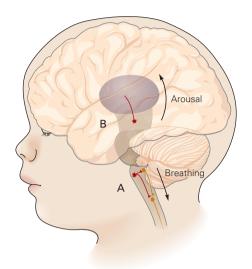

A widely held theory holds that some SIDS cases are due to defective CO₂ chemoreception, breathing, and arousal. An increase in the number of serotonergic

Figure 46–8 (Opposite) Serotonergic neurons have a role in the response to a rise in CO₂ levels as well as sudden infant death syndrome (SIDS).

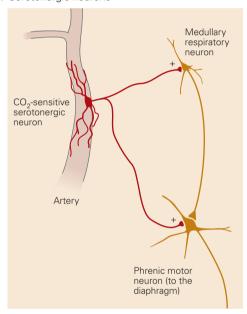

A. Serotonergic neurons in the medulla are central respiratory chemoreceptors that are thought to stimulate breathing in response to an increase in arterial blood PCO₂. The dendrites of these neurons wrap around large arteries and are stimulated by an increase in partial pressure of CO₂ (PCO₂) (see Figure 45–9). They project to and excite neurons in the medulla and spinal cord that control breathing.

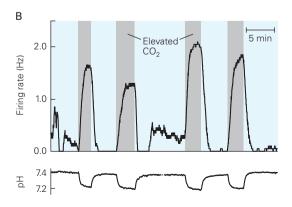

- **B.** Serotonergic neurons in the midbrain are also PCO_2 sensors. Shown here is the increase in firing rate of a serotonergic neuron from the dorsal raphe nucleus in response to an increase in PCO_2 (monitored by the resultant decrease in external pH). This increase in firing rate may convert thalamic and cortical neurons to single-spike mode and thus cause wakening from sleep, an important response to prevent airway obstruction during sleep when the airway is obstructed.
- C. 1. Infants are at risk of death from SIDS when three conditions coincide (triple risk hypothesis). First, the infant must be

vulnerable because of an underlying abnormality of the brain stem, such as a genetic predisposition or an environmental insult (eg, exposure to cigarette smoke). Second, the baby must be in the stage of development (usually less than 1 year of age) when it may be difficult to change position to escape airway obstruction. Third, there also must be an exogenous stressor (eg, lying face down in a pillow). (Reproduced, with permission, from Filiano and Kinney 1994.) 2. One proposed mechanism of SIDS is that the combination of abnormal serotonergic neurons (eg, caused by exposure to cigarette smoke) and postnatal immaturity of neurons involved in respiratory control may lead to the inability to respond effectively to airway obstruction. The infant then does not wake up and turn its head or breathe faster, either of which would correct the problem. As a result, severe decreases in blood oxygenation (hypoxia) and elevation of blood carbon dioxide (hypercapnia) occur. (Reproduced, with permission, from Richerson 2004.)

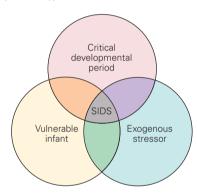

A Serotonergic neurons

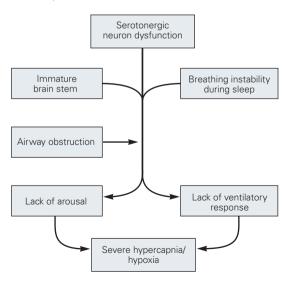

C Sudden Infant Death Syndrome

1 Triple risk hypothesis

2 Proposed mechanism

neurons with an immature morphology, a decrease in serotonin levels, and changes in serotonergic receptor density are found in the raphe nuclei of infants who die of SIDS. A plausible neurobiological mechanism for SIDS is that a defect in development of serotonergic neurons leads to reduced ability to detect a rise in partial pressure of CO₂ when airflow is obstructed during sleep, thus blunting the normal protective response which should include arousal and increased ventilation (Figure 46–8C). Infants sleeping face down would be unable to arouse sufficiently to change position when bedding blocks the airway. This mechanism could explain the success of the Back to Sleep campaign that encourages mothers to place infants on their backs when put to sleep and has reduced the incidence of SIDS by 50%.

Pain and Anti-nociceptive Pathways Are Modulated by Monoamines

Although pain is necessary for an animal to avoid injury, continued pain following an injury may be maladaptive (eg, if the pain prevents vigorous escape from a predator). Hence the monoaminergic systems include important descending projections to the dorsal horn of the spinal cord that modulate pain perception (see Chapter 24).

The noradrenergic inputs to the spinal cord originate from pontine cell groups, including the locus ceruleus, A5, and A7 cell groups. Similarly, the serotonergic medullary raphe nuclei, particularly the nucleus raphe magnus, project to the dorsal horn where they modulate the processing of information about noxious stimuli. Direct application of serotonin to dorsal horn neurons inhibits their response to noxious stimuli, and intrathecal administration of serotonin attenuates the defensive withdrawal of the paw evoked by noxious stimuli. In addition, intrathecal administration of antagonists of serotonin receptors blocks the pain inhibition evoked by stimulation of the raphe nuclei.

Insight into the role of serotonin in pain processing has been used in treating migraine headaches. In particular, agonists to the 5-HT_{1D} receptors, the triptans have been found to be therapeutically effective. One of the possible mechanisms of action of this family of tryptamine-based drugs includes presynaptic inhibition of pain afferents from the meninges, preventing sensitization of central neurons. Drugs that block monoamine reuptake, including both traditional antidepressants and selective serotonin reuptake inhibitors, are effective in limiting pain in patients with chronic pain and migraine headaches.

Monoamines Facilitate Motor Activity

The dopaminergic system is critical for normal motor performance. A massive projection ascends from the substantia nigra pars compacta to the striatum. As described in Chapter 43, dopaminergic fibers act on striatal neurons via D_1 and D_2 receptors to release inhibition on motor responses.

As would be expected, patients with Parkinson disease in whom midbrain dopaminergic neurons have degenerated have trouble initiating movement and difficulty sustaining their movements. Such patients speak softly, write with small letters, and take small steps. Conversely, drugs that facilitate dopaminergic transmission in the striatum can result in unintended behaviors ranging from motor tics (small muscle twitches), to chorea (large scale, jerky limb movements), to complex cognitive behaviors (such as compulsive gambling or sexual activity).

As first shown by Sten Grillner, serotonergic neurons play an important role in generating motor programs. Drugs that activate serotonin receptors can induce hyperactivity, myoclonus, tremor, and rigidity, which are all part of the "serotonin syndrome." Increases in the firing of raphe neurons have been observed in animals during repetitive motor activities such as feeding, grooming, locomotion, and deep breathing. Conversely, the atonia and lack of movement that occur during REM sleep are associated with near cessation of firing of raphe neurons.

Noradrenergic cell groups in the pons also send extensive projections to motor neurons. This modulatory input facilitates excitatory inputs to motor neurons by acting on β - and α_1 -adrenergic receptors. The sum of these effects is to facilitate motor neuron responses in stereotypic and repetitive behaviors such as rhythmic chewing, swimming, or locomotion. Conversely, increased β -adrenergic activation during stress can exaggerate motor responses and produce tremor. Drugs that block β -adrenergic receptors are used clinically to reduce certain types of tremor and are often taken by musicians prior to performances to minimize tremulousness.

An Overall View

The brain stem contains modulatory neurons with long axons that either ascend to the forebrain where they control various aspects of mood and cognition, or descend to the spinal cord where they regulate autonomic, somatosensory, or motor functions. These

monoaminergic and cholinergic systems are also essential components of the ascending arousal system.

The dual roles of the brain stem as a conduit for information flow to and from the forebrain and a modulator of forebrain activity is illustrated poignantly in patients with injury of the midpons. Because the ascending arousal system begins at the upper pontine level, patients remain awake; but the intact and awake forebrain is unable to interact with the external world other than with eye movements, a condition described clinically as the locked-in syndrome. In contrast, patients in a persistent vegetative state have intact brain stems but in most cases have extensive forebrain damage (such as from hypoxia). These patients appear to be alternately awake and asleep but have no outward signs of consciousness.

Hence, normal conscious behavior requires close interaction between the brain stem and the forebrain. The monoaminergic and cholinergic regulatory systems are very important in clinical medicine because their various components are dysfunctional in a variety of neurological and psychiatric diseases, including depression, dementia, migraine, psychosis, and SIDS. They are the targets of a large number of clinically useful drugs.

These neurons play a disproportionately important role in normal brain function and a better understanding of them has great potential for treating neuropsychiatric disease.

Postscript: Evaluation of the Comatose Patient

Nowhere is knowledge of brain stem anatomy and function more important in clinical neurology than when caring for the comatose patient. Coma is a state of profound unconsciousness from which the patient cannot be aroused by external stimuli. Two neurological principles are important for determining the cause of coma.

First, any decrease in the level of consciousness (decreased arousal) implies dysfunction of either both cerebral hemispheres or of the ascending arousal system (or its projections in the thalamus or hypothalamus). Second, one can pinpoint the levels of the brain stem that are damaged by determining abnormalities of reflexes mediated by cranial nerves, which often accompany coma.

The keys to successful care of a comatose patient are, first, to provide life support if needed, and then to identify the specific etiology of the coma. The cause of coma can usually be determined by obtaining a history from witnesses, an examination focused on brain stem function, and use of targeted laboratory tests. Dysfunction of the ascending arousal system can result either from diffuse impairment of the brain, usually from a pharmacologic, toxic, or metabolic cause, or from a focal lesion that impinges on the upper brain stem, diencephalon, or both cerebral hemispheres.

In the case of coma from diffuse impairment, there are few if any signs of focal brain stem defects. In the case of focal injuries to the upper brain stem or forebrain there are generally locally restricted changes, and the neurological examination can pinpoint the location and give clues to the cause of the problem.

Thus the neurological examination is the critical first step in determining the cause and severity of coma, and its primary purpose is to determine whether there is any evidence of a focal lesion and, if so, at what levels of the brain stem. The neurological examination of comatose patients is much simpler than that of conscious patients because it is not possible to do many portions of a full exam that require patient cooperation. This abbreviated neurological exam is sometimes called the *coma exam* or the *brain stem exam* and includes the following.

The *level of consciousness* is assessed by observing the motor response to external stimuli. If the patient is unable to respond to verbal stimuli or gentle shaking, it may be necessary to apply a local painful stimulus (eg, pressing on a nail bed). The level of consciousness is assessed by the vigor with which the patient responds to the stimulus. Terms used to describe responsiveness include *comatose*, *semi-comatose*, *obtunded*, *somnolent*, *lethargic*, and *alert*, in increasing order of preservation of arousal. However, it is generally more reproducible to describe how the patient responds to a stimulus rather than to use these inexact terms.

Asymmetric motor responses suggest a focal impairment of either the sensory or motor systems responsible for the side of the body that is less responsive but does not help identify the level of the lesion (Figure 46–9). Flexion of both arms at the elbow and extension of both legs, occurring spontaneously or in response to pain, is called decorticate posturing and usually indicates a lesion above the midbrain. Extension of both arms and both legs is called decerebrate posturing and usually indicates a more severe lesion that often affects the upper part of the brain stem.

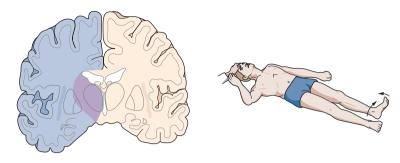

Abnormal respiratory patterns can help localize lesions and are important to recognize because they can predict whether a patient may later require mechanical ventilation (Figure 46–10). Periodic waxing and waning

Figure 46–9 The motor response to painful stimulation is a key localizing sign of brain damage in coma. Shown are the movements of the arms and legs in response to pressure on the supraorbital ridge, just above the eye.

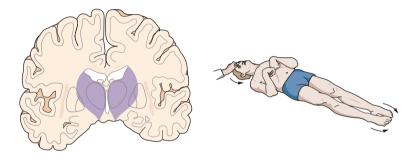

A. A patient with a diffuse metabolic encephalopathy (such as induced by high ammonia levels in the blood caused by liver failure) may respond to painful stimulation by trying to brush the examiner away. If there is a tumor or subdural hematoma in one hemisphere, the motor response may be asymmetric. The contralateral arm may not respond, the leg may be externally rotated, and stimulation of the sole of the foot may cause the big toe to flex upward (the Babinski reflex).

- B. Decorticate posturing is caused by damage at the junction of the diencephalon and the upper midbrain: the upper extremities flex, the lower extremities extend, and the toes extend down-
- C. Decerebrate posturing is caused by more extensive damage often extending into the midbrain, and results in extension of both the upper and lower extremities. Progression from decorticate to decerebrate posturing heralds rostrocaudal deterioration of the brain stem, which may progress rapidly to respiratory arrest because of involvement of the medulla.

A Swelling in one hemisphere compressing diencephalon

B Bilateral damage to diencephalon-upper midbrain

C Bilateral damage to upper midbrain

of respiration (Cheyne-Stokes breathing) can occur in forebrain depression. This must be differentiated from other irregular breathing patterns such as cluster or ataxic breathing, because the latter indicate damage to the lower brain stem and may require intubation.

Examination of cranial nerve function related to the pupillary light response and eye movements can be informative, because these pathways are closely adjacent to the structures of the ascending arousal system in the upper brain stem. The pupillary light reflex is tested by shining a bright light into one eye. Lesions at various levels of the brain stem produce characteristic changes in pupillary light responses that often can pinpoint the location of an injury (Figure 46–11).

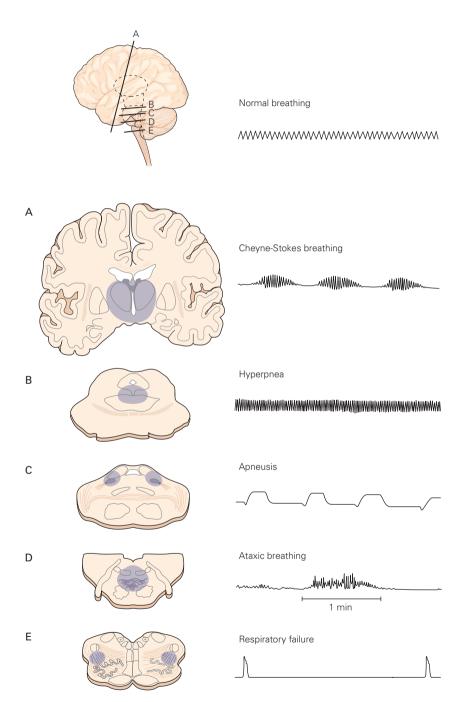

Eye movements can also be equally helpful. Slow, roving eye movements are seen in patients with diffuse forebrain impairment but normal brain stem activity. In a more deeply comatose patient, eye movements

can be elicited by turning the head, which induces a vestibular response that causes the eyes to rotate in the direction opposite to the movement (see Chapter 40) or by irrigating the external ear canal with cold water, which causes the eyes to turn toward that side. Lack of movement of both eyes toward one side indicates injury to the lower pons, where vestibular inputs reach the medial pontine circuitry that controls lateral gaze. Selective loss of abduction of one eye indicates damage to the abducens nerve, at the lower pontine level, whereas selective loss of conjugate adduction reflects injury to the medial longitudinal fasciculus, which travels in the medial part of the pons to the midbrain to connect the abducens and oculomotor nuclei. Selective loss of vertical eye movements implies an injury to the dorsal midbrain.

This brief explanation of the coma exam illustrates how it can often make it possible to determine

Figure 46–10 The respiratory pattern is a key indicator of the level of the brain that is not functioning properly in a comatose patient and provides a warning of impending respiratory arrest. The normal breathing pattern in an adult is regular, with approximately 14 to 16 breaths per minute while sitting quietly.

- A. Cheyne-Stokes breathing is a waxing and waning pattern of breaths interspersed with periods of apnea. This pattern can occur with bilateral cortical or diencephalic dysfunction, caused by either structural damage or depression by drugs or metabolic problems. Cheyne-Stokes breathing also occurs in patients with cardiac failure and is seen in most normal individuals while sleeping at moderately high altitude (see Chapter 45).
- B. Hyperpnea, or hyperventilation with deep, regular breaths, in comatose patients is most commonly caused by underlying medical problems (eg, liver failure, sepsis, or pulmonary edema). Rarely does it indicate a lesion in the central nervous system. Occasionally, central neurogenic hyperventilation is observed in patients with tumors of the brain stem (see Chapter 45).
- C. Apneusis is a pattern of deep, prolonged inspirations. This pattern occurs with lesions of the rostral pons in the region of the parabrachial complex (also known as the pneumotaxic center).
- **D.** Ataxic breathing is a pattern of breaths that are irregular in frequency, duration, and depth. It occurs with lesions of the pontomedullary junction and often heralds respiratory failure. It is important to recognize the difference between this pattern and Cheyne-Stokes breathing.
- E. Lesions of the rostral ventrolateral medulla cause respiratory failure. There may be occasional gasping breaths separated by long periods of apnea, until respiration ceases entirely.

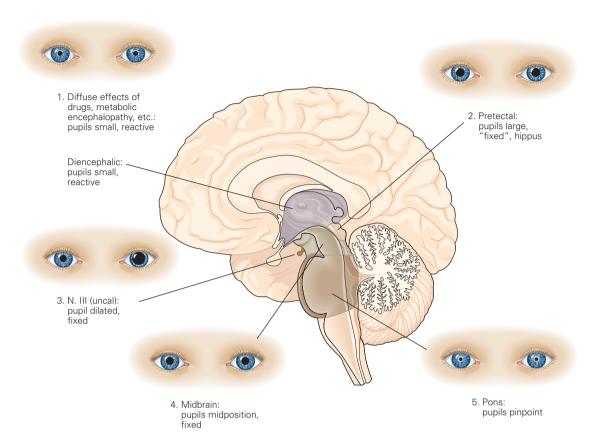

Figure 46–11 The pupillary light reflex is an important sign for determining the level of a brain stem lesion. In patients with depressed consciousness caused by metabolic encephalopathy, drug ingestion, or diffuse pressure on the diencephalon, the pupils are slightly smaller than normal but respond vigorously to light (1). Pressure on the pretectal area (eg, from a pineal tumor) prevents light from causing pupillary constriction and results in large, unreactive pupils (2). Injury to the oculomotor nerve (N. III) can occur because of swelling in the ipsilateral cerebrum (eg, from a brain tumor), which causes the uncus (the medial edge of the temporal lobe) to herniate through the tentorial opening and crush the oculomotor nerve. This first leads to a large, unreactive pupil in the affected eye

(3). It can also later cause the affected eye to deviate laterally. This blown pupil is an ominous sign that the brain stem is about to be compressed from above. Damage to the midbrain tegmentum causes complete loss of pupillary response to light (4), but the pupils may dilate if a painful stimulus (eg, pinching the neck) is applied because of a sympathetic response (the ciliospinal response). Injury to the pons results in pinpoint pupils (5), which can be seen with a magnifying lens to respond slightly to light. Pontine injury not only disrupts the descending hypothalamic pupillodilator pathway but also interrupts ascending inputs to the Edinger-Westphal nucleus that inhibit its tone.

the precise level of the affected brain stem. Such information provides important clues as to the type of the injury and the kind of immediate treatment and further evaluation that may be required.

An Overall View

HEN WE ARE FRIGHTENED OUR HEART races, our breathing becomes rapid and shallow, our mouth becomes dry, our muscles tense, our palms become sweaty, and we may want to run. These bodily changes accompanying fear are mediated by the autonomic motor system, which controls

heart muscle, smooth muscle, and exocrine glands. The autonomic motor system is controlled by a central neuronal network that includes the hypothalamus.

As we shall learn in this and the next two chapters, the hypothalamus regulates the autonomic circuits so as to recruit appropriate physiological responses for specific emotions and to coordinate these physiological and emotional responses with other aspects of behavior to insure constancy of the internal environment (homeostasis). The hypothalamus contributes to the maintenance of homeostasis by acting on three major systems: the autonomic motor system, the endocrine system, and an ill-defined neural system concerned with motivation.

The autonomic motor system is distinct from the somatic motor system, which controls skeletal muscle. Nevertheless, to produce behaviors the somatic and autonomic motor systems must work together. Whereas neurons in the somatic motor system regulate contractions of striated muscles (see Chapter 34), the autonomic motor system regulates gland cells as well as smooth and cardiac muscle, maintains constant body temperature, and controls eating, drinking, and sexual behavior.

Although the autonomic motor system is largely involuntary, the behaviors controlled by it are tightly integrated with voluntary movements controlled by the somatic motor system. Running, climbing, and lifting are voluntary actions with metabolic requirements and thermoregulatory consequences that are automatically met by the autonomic system through changes in cardiorespiratory drive, cardiac output, regional blood flow, and ventilation. Autonomic behaviors

similarly are linked to emotional arousal, stress, motivation, and defensive reactions. Feelings of fear, anger, happiness, and sadness have characteristic autonomic manifestations.

In this chapter we first examine the peripheral components of the autonomic system and then their role in mediating behaviors. We then explore how these "autonomic behaviors" are orchestrated through a central autonomic network in the brain stem and hypothalamus. We conclude by considering the role of the amygdala and specialized areas of cerebral cortex in coordinating autonomic function with motivation, volition, and emotion. The autonomic and hypothalamic mechanisms involved in emotion and motivation are examined in more detail in the next two chapters.

The Autonomic Motor System Mediates Homeostasis

In the middle of the 19th century Claude Bernard in Paris drew attention to the stability of the body's internal environment, which includes the "fluid that surrounds and bathes all tissues," during a broad range of behavioral states and external conditions. Bernard wrote: "The internal environment (*le milieu interior*) is a necessary condition for a free life." Building on this idea, in the 1930s Walter B. Cannon introduced the concept of homeostasis to describe the mechanisms that maintain within a narrow physiological range the constancy of composition of the bodily fluids, body temperature, blood pressure, and other physiological variables.

As envisioned by Cannon, homeostatic mechanisms are adaptive because they extend the range of human behavior. For example, during exercise healthy people can increase their cardiac output four- to fivefold while maintaining blood pressure within a much narrower range. In the absence of these normal compensatory changes, blood pressure would increase in direct proportion to cardiac output, and the resulting increase in pressure would rupture blood vessels, perturb fluid composition, and alter the balance among the vascular, interstitial, and intracellular compartments. Increases in pressure of that proportion do not normally happen because the increase during exercise is curbed by an increase in diameter of the arteries that supply the working muscles and a resulting reduction of total vascular resistance to blood flow.

All homeostatic behavior, including control of the circulation, arises from neural modulation of the physiological properties of organ systems, mediated by hypothalamic control of the autonomic motor system and the endocrine system. We begin the discussion of these mechanisms by considering the peripheral components: the autonomic ganglia. The circuits of the ganglia connect with the spinal cord and brain stem and mediate simple reflexes that are the components of more complex behaviors.

The Autonomic System Contains Visceral Motor Neurons That Are Organized into Ganglia

Unlike the somatic motor system, in which the motor neurons are located in the ventral spinal cord and brain stem, the cell bodies of autonomic motor neurons are found in enlargements of peripheral nerves called *ganglia*. The autonomic ganglia contain motor neurons that innervate the secretory epithelial cells in glands or smooth and cardiac muscle.

Overall, the nervous system has many more autonomic than somatic motor neurons. In humans the entire spinal cord contains only approximately 120,000 somatic motor nerve cells, whereas the superior cervical ganglion alone contains approximately 900,000 autonomic motor neurons. Although the significance of this difference in numbers is uncertain, it may reflect the great diversity and complexity of autonomically controlled target tissues—the stomach, intestine, bladder, heart, lungs, and vasculature—as compared to the relative uniformity of skeletal muscle controlled by the somatic motor system. Most autonomic ganglia contain far fewer cells. For example, in the lungs and gastrointestinal tract of humans there are many microscopic ganglia, each with only tens to hundreds of neurons. These differences in number of cells are thought to reflect differences in the degree of control and the size of peripheral target fields.

Efforts to understand the principles of organization of autonomic ganglia began in 1880 in England with the work of Walter Gaskell and were later continued by John N. Langley. Their pioneering studies determined how individual autonomic ganglia are functionally regulated by central nerves, and in turn how the different ganglia regulate different peripheral

¹The peripheral nerves also have sensory ganglia, located on the dorsal roots of the spinal cord and on five of the cranial nerves: trigeminal (V), facial (VII), vestibulocochlear (VIII), glossopharyngeal (IX), and vagus (X) (see Chapter 45).

Brain stem and Sympathetic and Effector cells spinal cord parasympathetic ganglia Smooth muscle cell Gland cell Preganglionic Cardiac neurons muscle Postganglionic neurons

Figure 47–1 Autonomic pathways have three basic cell types. Autonomic motor neurons lie outside the central nervous system in clusters or ganglia and are controlled by preganglionic neurons in the spinal cord and brain stem. Specialized neurons in ganglia regulate specific types of effector cells, such as smooth muscle, gland cells, and cardiac muscle.

targets. Gaskell and Langley stimulated autonomic nerves and observed the responses of end-organs (eg, vasoconstriction, piloerection, sweating, pupillary constriction). They used nicotine to block signals from individual ganglia to test interactions between ganglia. In the course of these studies Langley proposed that specific chemical substances must be released by neurons of the autonomic ganglia and that these substances act by binding to receptors on the target cells. These ideas set the stage for the later investigations of chemical synaptic transmission. Langley also distinguished the autonomic and somatic motor systems and in so doing created much of our current nomenclature.

Langley divided the autonomic system into three divisions: sympathetic, parasympathetic, and enteric. All neurons in sympathetic and parasympathetic ganglia are controlled by *preganglionic* neurons whose cell bodies lie in the spinal cord and brain stem. The pre-ganglionic neurons synthesize and release the neurotransmitter acetylcholine (ACh), which acts on nicotinic ACh receptors in *postganglionic* neurons, producing fast excitatory postsynaptic potentials and initiating action potentials that propagate to synapses with effector cells in *end-organs* (Figure 47–1). The sympathetic and parasympathetic systems are distinguished by five criteria:

- 1. The segmental organization of their preganglionic neurons in the spinal cord and brain stem
- 2. The peripheral locations of their ganglia
- 3. The types and locations of end-organs they innervate
- 4. The effects they produce on end-organs
- 5. The neurotransmitters employed by their post-ganglionic neurons

Preganglionic Neurons Are Localized in Three Regions Along the Brain Stem and Spinal Cord

The parasympathetic pathways arise from a cranial nerve zone in the brain stem and a second zone in sacral segments of the spinal cord (Figure 47–2). These parasympathetic zones surround a sympathetic zone that extends continuously in thoracic and lumbar segments of the cord.

The cranial parasympathetic pathways arise from preganglionic neurons in the general visceral motor nuclei of four cranial nerves: the oculomotor nerve (N. III) in the midbrain and the facial (N. VII), glossopharyngeal (N. IX), and vagus (N. X) nerves in the medulla. The cranial parasympathetic nuclei are described in Chapter 45 together with the mixed cranial nerves (such as the facial, glossopharyngeal, and vagus). The spinal parasympathetic pathway originates in preganglionic neurons in sacral segments two to four (S2–S4). The cell bodies of most of these neurons are located in intermediate regions of the gray matter, and their axons project in peripheral nerves through the ventral roots.

The sympathetic preganglionic cell column extends between the cervical and lumbosacral enlargements of the spinal cord, corresponding to the first thoracic segment (T1) and third lumbar segment (L3) in humans (Figure 47–2). Most of the cell bodies of sympathetic preganglionic neurons are located in the intermediolateral cell column, near the lateral margin of the spinal gray matter at the level of the central canal (Figure 47–3). Others are found in the central autonomic area surrounding the central canal and in a band connecting the central area with the intermediolateral cell column. The axons of preganglionic sympathetic neurons project from the spinal cord through the nearest ventral

root and then run with small connecting nerves known as *rami communicantes* before terminating on postganglionic cells in the paravertebral sympathetic chain (Figure 47–3).

Sympathetic Ganglia Project to Many Targets Throughout the Body

The sympathetic motor system regulates systemic physiological parameters such as blood pressure and body temperature by influencing target cells within virtually every tissue throughout the body (Figure 47–2). This regulation depends on afferent pathways from the spinal cord and from supraspinal structures that control the activity of the preganglionic neurons. Preganglionic neurons form synapses with neurons in paravertebral and prevertebral sympathetic ganglia (Figure 47–3) that in turn form synapses with a variety of end-organs, including blood vessels, heart, bronchial airways, piloerector muscles, and salivary and sweat glands. The preganglionic neurons also synapse on chromaffin cells in the medulla of the adrenal gland

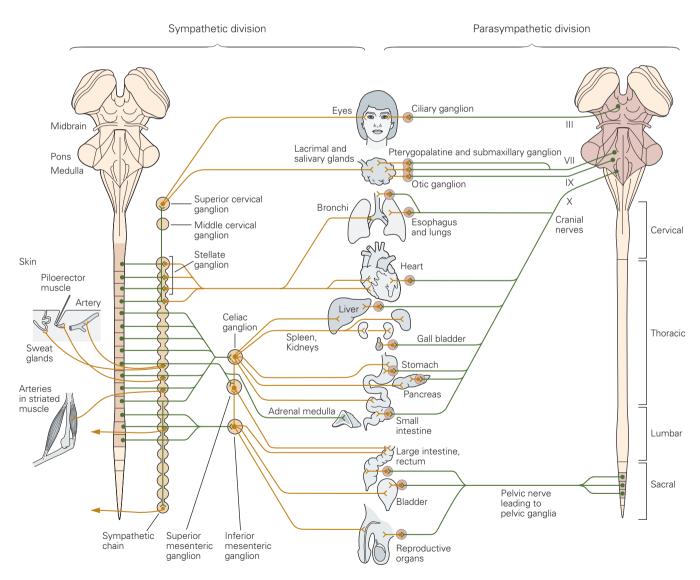

Figure 47–2 Sympathetic and parasympathetic divisions of the autonomic motor system. The sympathetic ganglia lie close to the spinal column and supply virtually every tissue in the body. Some tissues, such as skeletal muscle, are regulated

only indirectly through their arterial blood supply. The parasympathetic ganglia are found in close apposition with their targets, which do not include the skin or skeletal muscle.

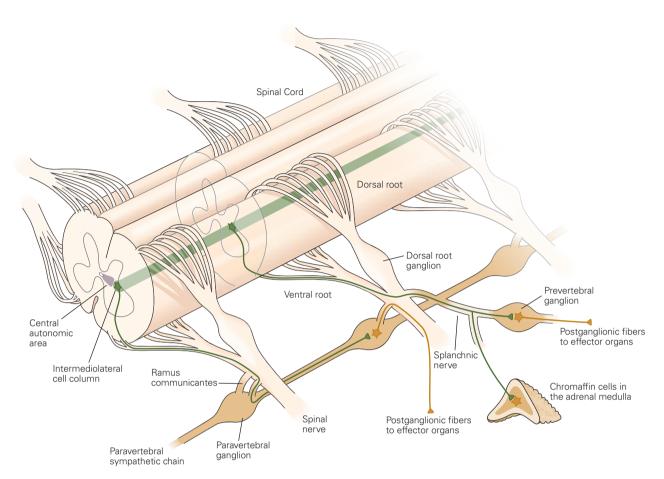

Figure 47–3 The sympathetic outflow is organized into groups of paravertebral and prevertebral ganglia. The axons of preganglionic cells in the spinal cord reach postganglionic neurons by way of ventral roots and the paravertebral sympathetic chain. The axons either form synapses on postganglionic

neurons in paravertebral ganglia or project out of the chain into splanchnic nerves. Preganglionic axons in the splanchnic nerves form synapses with postganglionic neurons in prevertebral ganglia and with chromaffin cells in the adrenal medulla.

(Figure 47–3), which secrete epinephrine (adrenaline) and norepinephrine (noradrenaline) into the circulation as hormones to act on distant targets.

The paravertebral and prevertebral sympathetic ganglia differ both in location and organization. Paravertebral ganglia are distributed segmentally, extending bilaterally as two chains from the first cervical segment to the last sacral segment. The chains lie lateral to the vertebral column at its ventral margin and generally contain one ganglion per segment (Figures 47–2 and 47–3). Two important exceptions are the superior cervical and stellate ganglia. The superior cervical ganglion is a coalescence of several cervical ganglia and supplies sympathetic innervation to the entire head, including the cerebral vasculature. The stellate ganglion, which innervates the heart and

lungs, is a coalescence of ganglia from lower cervical segments and the first thoracic segment. These sympathetic pathways have an orderly somatotopic relation to one another, from their segmental origin in preganglionic neurons to their terminus in peripheral targets.

The prevertebral ganglia are midline structures that lie close to the arteries for which they are named (Figures 47–2 and 47–3). In addition to sending sympathetic signals to visceral organs in the abdomen and pelvis, these ganglia also receive sensory feedback from their end-organs.

Parasympathetic Ganglia Innervate Single Organs

In contrast to sympathetic ganglia, which regulate many targets and lie some distance from their targets close to the spinal cord, parasympathetic ganglia generally innervate single end-organs and lie near to or within the end-organs they regulate (Figure 47–2). In addition, the parasympathetic system does not influence skin or skeletal muscle except in the head, where it regulates vascular beds in the jaw, lip, and tongue.

The cranial and sacral parasympathetic ganglia innervate different targets. The cranial outflow includes four ganglia in the head. The oculomotor (III) nerve projects to the ciliary ganglion, which controls pupillary size and focus by innervating the iris and ciliary muscles. The facial (VII) nerve and a small component of the glossopharyngeal (IX) nerve project to the pterygopalatine (or sphenopalatine) ganglion, which promotes production of tears by the lacrimal glands and mucus by the nasal and palatine glands. Cranial nerve IX and a small component of nerve VII project to the otic ganglion, which innervates the parotid, the largest salivary gland. Nerve VII also projects to the submandibular ganglion, which controls secretion of saliva by the submaxillary and sublingual glands.

The vagus (X) nerve projects broadly to parasympathetic ganglia in the heart, lungs, liver, gall bladder, and pancreas. It also projects to the stomach, small intestine, and more rostral segments of the gastrointestinal tract. The caudal parasympathetic outflow supplies the large intestine, rectum, bladder, and reproductive organs.

The Enteric Ganglia Regulate the Gastrointestinal Tract

The entire gastrointestinal tract, from the esophagus to the rectum—and including the pancreas and gall bladder—is controlled by the system of enteric ganglia. This system, by far the largest and most complex division of the autonomic nervous system, contains as many as 100 million neurons in humans.

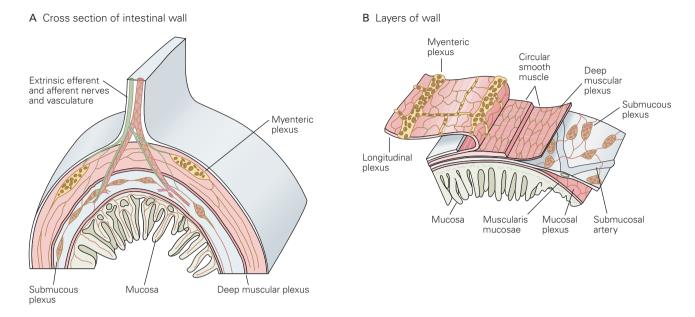

The enteric system has been studied most extensively in the small intestine of the guinea pig, where the diversity of enteric neurons and their organization has been analyzed in two interconnected plexuses, small islands of interconnected neurons. The myenteric plexus controls smooth muscle movements of the gastrointestinal tract; the submucous plexus controls mucosal function (Figure 47–4). Working together, this distributed network of ganglia coordinates the orderly peristaltic propulsion of gastrointestinal contents and controls the secretions of the stomach and intestines and other components of digestion. In addition, the enteric system regulates local blood flow and is modulated by external inputs from sympathetic prevertebral ganglia and from parasympathetic components of the vagus nerve.

Unlike the sympathetic and parasympathetic divisions of the autonomic nervous system, the enteric ganglia contain interneurons and sensory neurons in addition to motor neurons. This intrinsic neural circuitry can maintain the basic functions of the gut even after the splanchnic sympathetic and vagal parasympathetic pathways are cut. Through splanchnic nerves and the vagus nerve the gastrointestinal tract also sends sensory information about the physiological states of the tract to the spinal cord and brain stem.

Both the Pre- and Postsynaptic Neurons of the Autonomic Motor System Use Co-Transmission at Their Synaptic Connections

Synaptic transmission in the peripheral autonomic nervous system was originally thought to be a simple tale of two neurotransmitters, ACh and norepinephrine. According to this idea, all preganglionic neurons in the sympathetic and parasympathetic systems use ACh as their neurotransmitter, binding and exciting ionotropic nicotinic ACh receptors on ganglionic neurons and thus opening nonselective cation channels similar to the nicotinic ACh receptors at the neuromuscular junction. The resulting action potentials propagate to postganglionic synapses with end-organs in the periphery. At these synapses parasympathetic neurons release ACh that activates muscarinic receptors whereas sympathetic neurons release norepinephrine that activates α - and β -adrenergic G protein-coupled receptors. The consequences can be either excitatory or inhibitory, depending on the type of target cell and its receptors (Table 47–1).

In addition to acting on different receptors in different postsynaptic cells, one transmitter can activate two or more receptor types in the same postsynaptic cell. This principle was first discovered in sympathetic ganglia where ACh activates both nicotinic and muscarinic postsynaptic receptors to produce both a fast and slow excitatory postsynaptic potential (EPSP) (Figure 47–5A, and see Chapter 13). In some cases one transmitter can activate both a postsynaptic receptor as well as a receptor on the presynaptic terminals from which the transmitter was released. Such presynaptic responses can either reduce transmitter release (presynaptic inhibition) or enhance it (presynaptic facilitation). This mechanism, also widespread, was discovered at autonomic junctions with blood vessels where different types of α-adrenergic receptors are expressed by some pre- and postsynaptic cells (Figure 47–5B). This specialization of synaptic transmission

C Laminar distribution of neurons within the intestinal wall

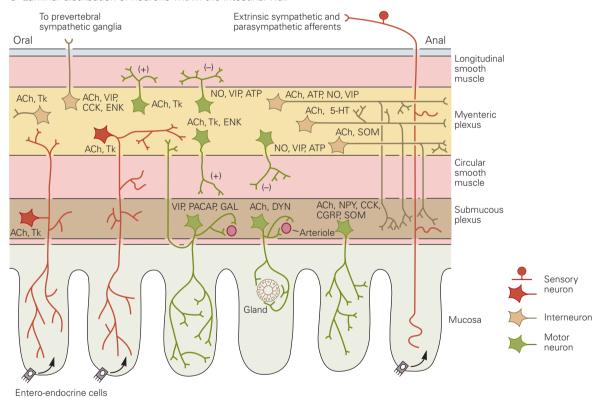

Figure 47–4 Organization of the enteric plexuses in the guinea pig. The myenteric plexus and submucous plexus lie between the layers of intestinal wall (A and B). At least 14 types of neurons have been identified within the enteric system based on morphology, chemical coding, and functional properties (C). Four sets of motor neurons provide excitatory (+) and inhibitory (–) inputs to two smooth muscle layers. Three additional groups of motor neurons control secretions from the mucosa and produce vasodilation. The network also includes

two major classes of intrinsic sensory neurons. (ACh, acetylcholine; ATP, adenosine triphosphate; CCK, cholecystokinin; CGRP, calcitonin gene-related polypeptide; DYN, dynorphin; ENK, enkephalin; GAL, galanin; NPY, neuropeptide Y; NO, nitric oxide; PACAP, pituitary adenylate cyclase-activating peptide; SOM, somatostatin; Tk, tachykinin; VIP, vasoactive intestinal peptide; 5-HT, serotonin.) (Parts A and B adapted, with permission, from Furness and Costa 1980; Part C reproduced, with permission, from Furness et al. 2004.)

Table 47-1 Autonomic Neurotransmitters and Their Receptors

Transmitter	Receptor	Responses
Norepinephrine	α_1	Stimulates smooth muscle contraction in arteries, urethra, gastrointestinal tract, iris (pupillary dilation), uterine contractions during pregnancy, ejaculation; glycogenolysis in liver; glandular secretion (salivary glands, lacrimal glands)
	α_2	Presynaptic inhibition of transmitter release from sympathetic and parasympathetic nerve terminals; stimulates contraction in some arterial smooth muscle
	$oldsymbol{eta}_1$	Increases heart rate and strength of contraction
	eta_2	Relaxes smooth muscle in airways and gastrointestinal tract; stimulates glycogenolysis in liver
	$oldsymbol{eta}_3$	Stimulates lipolysis in fat cells; inhibits bladder contraction
Acetylcholine	Nicotinic	Fast EPSP in autonomic ganglion cells
	Muscarinic: M ₁ , M ₂ , M ₃	Glandular secretion; ocular circular muscle (pupillary constriction); ciliary muscles (focus of lens); stimulates endothelial production of NO and vasodilation; slow EPSP in sympathetic neurons; slows heart rate; presynaptic inhibition at cholinergic nerve terminals; bladder contraction; salivary gland secretion
Neuropeptide Y	Y ₁ , Y ₂	Stimulates arterial contraction and potentiates responses mediated by α_1 -adrenergic receptors; presynaptic inhibition of transmitter release from some postganglionic sympathetic nerve terminals
Nitric oxide	Diffuses through mem- branes; often acts to stimulate intracellular soluble guanylate cyclase	Vasodilation, penile erection, urethral relaxation
Vasoactive intestinal peptide	VIPAC1, VIPAC2	Glandular secretion and dilation of blood vessels supplying glands
ATP	P_{2X} , P_{2Y}	Fast and slow excitation of smooth muscle in bladder, vas deferens, and arteries

ATP, adenosine triphosphate; EPSP, excitatory postsynaptic potential; NO, nitric oxide.

in sympathetic and parasympathetic neurons leads to functional diversity in the regulation of end-organ function.

Today we know that many transmitters are coreleased at a single synapse, activating multiple receptor types and contributing to functional diversity. Many autonomic neurons release co-transmitters, often together with ACh or norepinephrine.

The cellular principles of co-transmission have been elucidated in part in a series of studies of paravertebral sympathetic ganglia in the bullfrog. These ganglia contain two major groups of neurons. Secretomotor B neurons selectively innervate mucous glands in the skin, whereas vasomotor C neurons selectively innervate arteries that supply striated muscle and skin. In addition, each cell group receives input from a distinct group of preganglionic neurons in the spinal cord. These cell types differ from one another in part by expressing different neuropeptides. Preganglionic B cells selectively express calcitonin gene-related peptide (CGRP). Preganglionic C neurons express luteinizing hormone-releasing hormone (LHRH), also known as gonadotropin-releasing hormone (GnRH), and their postganglionic target cells express neuropeptide Y (Figure 47–6A).

The co-release of LHRH and ACh by the preganglionic C neurons was discovered in 1979 by Stephen Kuffler with Lily Jan and Yuh Nung Jan. This discovery

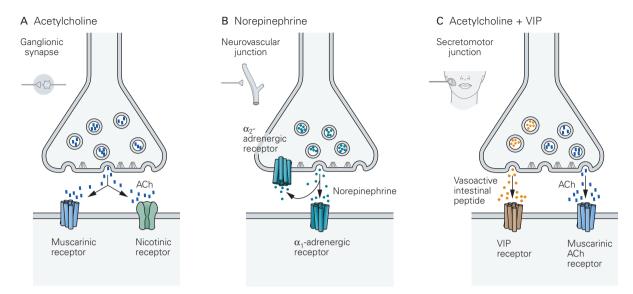

Figure 47–5 Synaptic transmission in the peripheral autonomic system.

A. In sympathetic ganglia ACh can activate both nicotinic and muscarinic receptors to produce fast and slow postsynaptic potentials, respectively.

B. At neurovascular junctions norepinephrine can simultaneously activate postsynaptic α_1 -adrenergic receptors to produce vasoconstriction and presynaptic α_2 -adrenergic receptors to inhibit further transmitter release.

Figure 47–6 (Opposite) Synaptic organization of the paravertebral sympathetic system in the bullfrog. The synaptic specialization of neurons that control different peripheral targets have been studied in paravertebral sympathetic ganglia associated with spinal segments 9 and 10. These amphibian ganglia are also a model system for analyzing synaptic co-transmission and its role in synaptic integration in the autonomic ganglia.

A. The secretomotor B and vasomotor C circuits originate in separate spinal segments, traverse the same ganglia, and then control different targets. In addition to their unique projection patterns, the two cell types co-release different neuropeptides along with acetylcholine (ACh). (CGRP, calcitonin gene-related peptide; GIRK, G protein-coupled inward-rectifying K⁺ channel; LHRH, luteinizing hormone-releasing hormone.) (Adapted, with permission, from Horn and Stofer 1989.)

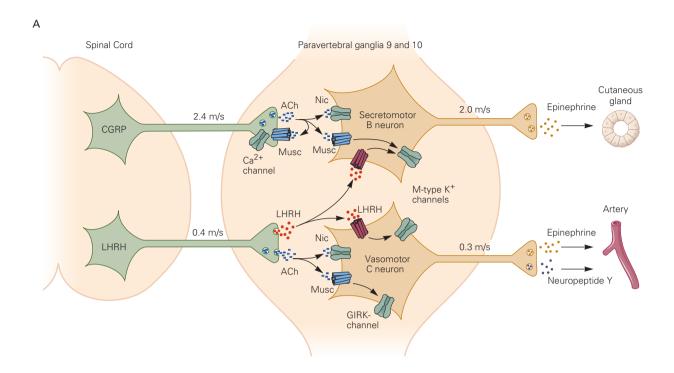

B. Synaptic events span a 3,000-fold range of time scales and differ in the stimulus patterns that are effective. 1. The nicotinic excitatory postsynaptic potential (EPSP) in all ganglionic neurons is readily evoked by a single presynaptic stimulus and lasts for 50 ms. 2. The muscarinic inhibitory postsynaptic potential (IPSP) in C neurons is caused by activation of G protein-coupled inward-rectifying K⁺ channels (GIRK), is 50 times slower than the fast EPSP, and summates during repetitive stimulation.

3. The neuropeptide luteinizing hormone releasing hormone (LHRH) is released by preganglionic C neurons and evokes a very slow EPSP in postganglionic B and C neurons due to its diffusion throughout the ganglion. Note the different time scales in 1–3. Neuropeptide release is greatly enhanced by high-frequency repetitive stimulation and produces a slow EPSP that is 60 times slower than the muscarinic IPSP.

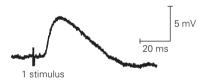

C. Co-transmission involves the co-activation of more than one type of receptor by more than one transmitter. Parasympathetic postganglionic nerve terminals in the salivary glands release both ACh and vasoactive intestinal peptide (VIP) to control secretion. Autonomic synapses with end-organs sometimes employ more elaborate combinations, activating three or more receptor types.

4. The muscarinic EPSP in B neurons is also slow and optimally elicited by repetitive stimulation. 5. Finally, ACh released by preganglionic B neurons can bind presynaptic receptors. The operation of these presynaptic receptors can be demonstrated by activating them with the drug muscarine and recording the effect on fast nicotinic excitatory postsynaptic currents (EPSCs) under voltage-clamp elicited by stimulating the preganglionic nerve. The muscarine produces two effects. The upper trace shows the downward deflection of the baseline caused by activation of a slow excitatory inward postsynaptic current; the lower records show the reduction in amplitude of the EPSC caused by inhibition of the ACh released by the preganglionic B neurons. (Reproduced, with permission, from Adams and Brown 1982; reproduced, with permission, from Dodd and Horn 1983; reproduced, with permission, from Karila and Horn 2000; reproduced, with permission, from Peng and Horn 1991; reproduced, with permission, from Shen and Horn 1996.)

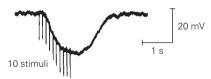

C. The consequences of synaptic integration in ganglia 9 and 10 can be studied by selectively stimulating preganglionic inputs to B or C neurons and observing the responses of mucous glands in the skin and of the abdominal aorta. A single preganglionic stimulus applied to the B pathway activates the mucous glands (measured by voltage drop across the skin). Multiple preganglionic stimuli applied to the C pathway evoke vasoconstriction (measured here by muscle tension). (Reproduced, with permission, from Jobling and Horn 1996; reproduced, with permission, from Thorne and Horn 1997.)

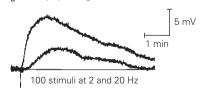

B₁ Fast nicotinic EPSP in B and C cells

Synaptic activation of vasoconstriction by preganglionic C pathway

illustrated three general principles, establishing LHRHmediated synaptic transmission as a model for other neuropeptide actions. First, peptides can mediate very slow synaptic events, even slower than those caused by muscarinic ACh receptor stimulation. Although mammalian preganglionic neurons do not express LHRH, they release other neuropeptides that produce slow synaptic actions similar to those seen in bullfrog sympathetic ganglia. Second, peptides act diffusely at a distance and thereby provide cross talk between different sympathetic cell types. Although LHRH is released by preganglionic inputs to C cells that do not form synapses with B cells (Figure 47-6A), it can diffuse many micrometers to activate LHRH receptors on adjacent B neurons. Finally, different transmitters can share intracellular signaling pathways. For example, the actions of LHRH both resemble and block the excitatory, muscarinic response to ACh in B cells (a process called *cross-desensitization*).

Studies of bullfrog sympathetic ganglia also illustrate how preganglionic release of ACh can co-activate different forms of muscarinic (slow) responses together with the nicotinic (fast) EPSP. The muscarinic responses include a slow EPSP in B neurons, a slow inhibitory postsynaptic potential (IPSP) in C neurons, and inhibition of ACh release from preganglionic nerve terminals in the B cell system (Figure 47–6B). Each of these events arises through regulation of different ion channels. In both mammalian and amphibian sympathetic neurons the slow EPSP is mediated by suppression of the voltage-gated M-type K⁺ channel belonging to the KCNQ (K_v9) family. The slow IPSP is produced by activation of G protein-coupled, inward-rectifying K⁺ channels (GIRKs) (K_{ir}3), and presynaptic inhibition by inhibition of N-type voltage-gated Ca²⁺ channels (Ca_v2.2).

The time courses of the fast and slow synaptic events reflect fundamental differences in synaptic signaling mechanisms. The EPSPs initiated by the nicotinic ACh receptors are brief, lasting 10 to 50 ms because ionotropic receptor-channels are directly gated by ligand binding (see Figure 8–9). In contrast, synaptic events initiated at metabotropic receptors—the muscarinic ACh, peptide, and epinephrine receptors as well as a type of adenosine triphosphate (ATP) receptor (P_{2X})—are slow, with time courses lasting hundreds of milliseconds to minutes, because the receptor and ion channel are coupled by a multistep signaling cascade (see Chapter 11).

The final motor responses elicited by all three divisions of the autonomic system also depend on the properties of synaptic transmission at neuro-effector junctions. In particular they depend on the identity of postganglionic neurotransmitters and the pre- and

postsynaptic receptors (Table 47–1). Understanding the pharmacology of these receptors and the second-messenger signaling pathways they control is important in the treatment of numerous medical conditions, including hypertension, heart failure, asthma, emphysema, allergies, sexual dysfunction, and incontinence.

Here again co-transmission is operative. Acetylcholine and vasoactive intestinal peptide (VIP) are frequently co-released from neurons that control glandular secretion (Figure 47–5C). In salivary glands, for example, the two transmitters act directly to evoke secretion. In addition, VIP causes dilation of the blood vessels supplying the gland. Because co-transmitters can be released in varying proportions that depend on the frequency of presynaptic firing, different patterns of activity can regulate the volume of secretions, their protein and water content, and their viscosity. This regulation operates both through a direct effect on the glandular blood flow that provides the water contained in secretions.

Autonomic Behavior Is the Product of Cooperation Between All Three Autonomic Divisions

To survive, animals and humans must have a "fight-or-flight" response that prepares an animal to stand and fight a predator or run away and live to see another day. Walter Cannon, in addition to introducing the concept of homeostasis, also appreciated that this "fight-or-flight" response is a critical sympathetic function.

Two important ideas underlie this insight. First, the sympathetic and parasympathetic systems play complementary, even antagonistic, roles; the sympathetic system promotes arousal, defense, and escape, whereas the parasympathetic system promotes eating and procreation. Second, actions of the sympathetic system are diffuse; they influence all parts of the body and once turned on can persist for some time. These ideas are behind the popular notion of the "adrenaline rush" produced by excitement, as by a roller coaster ride.

We now know that extreme sympathetic responses such as the "fight-or-flight" response can have long-term pathological consequences resulting in the syndrome known as post-traumatic stress disorder (see Chapter 63). This disorder was first recognized in soldiers during World War I when it was referred to as "shell shock." A variety of life-threatening experiences, ranging from sexual abuse and domestic violence to aircraft disasters, can also induce post-traumatic stress disorder,

a disorder that affects millions of people in the United States alone.

Because the fight-or-flight model assumes antagonistic roles for the sympathetic and parasympathetic systems, Cannon's model led to an overemphasis on the extremes of autonomic behavior. Actually during everyday life the different divisions of the autonomic system are tightly integrated. In addition, we now know that the sympathetic system is less diffusely organized than first envisioned by Cannon. Subsets of neurons even within the sympathetic division control specific targets, and these pathways can be activated independently.

As in the somatic motor system, reflexes in the autonomic motor system are elicited through sensory pathways and are hierarchically organized. The simplest feedback loops are confined to the periphery and spinal cord, whereas more complex loops extend to higher centers. An important feature of this organization is that it allows for coordination between the different divisions of the autonomic system. The interplay between different systems in simple autonomic behaviors is analogous to the role of antagonist muscles in locomotion. To walk, one must alternately contract antagonist muscles that flex and extend a joint. Similarly, the sympathetic and parasympathetic systems are often partners in the regulation of end-organs. In most cases, ranging from the simplest reflexes to more complex behaviors, all three peripheral divisions of the autonomic system work together.

We illustrate this organization with three examples: contractions of the gut (peristalsis), control of the bladder (micturition reflex), and regulation of blood pressure.

Peristalsis

Peristalsis of circular smooth muscle normally propels the contents of the gastrointestinal tract in the oralanal direction. This coordinated motor program is generated locally by the enteric neural network (Figure 47–4C) and can be elicited as a simple reflex by passive distension of the gut wall. The reflex activates excitatory motor neurons located rostral (oral) to the stimulus and inhibitory motor neurons located caudal (anal) to the stimulus. The synaptic connections between antagonistic motor neurons and sensory neurons are so arranged that the enteric network can build a cycle of contraction and relaxation that propagates in unidirectional waves of contractions.

The sensory information required to initiate the basic reflex originates in and is integrated locally within the enteric network. Two groups of sensory neurons

in the system provide additional feedback to higher centers. One group lies in the dorsal root ganglia and projects from the gut to the prevertebral sympathetic ganglia and into the spinal cord and ascending pathways. The other group projects through the vagus nerve to sensory neurons in the brain stem. These pathways signal hunger and satiety. In response, the central nervous system can enhance or inhibit digestion through excitatory parasympathetic efferents in the vagus nerve and inhibitory sympathetic efferents in prevertebral splanchnic nerves.

Micturition Reflex

The micturition reflex is another example of a physiological cycle resulting from coordination between sympathetic and parasympathetic systems. In this cycle the bladder is emptied by the parasympathetic pathway, which contracts the bladder and relaxes the urethra. The sympathetic system allows the bladder to fill by stimulating the urethra and inhibiting the parasympathetic pathway, thus inhibiting the reflex for bladder emptying. The sensory feedback required for this behavior is integrated with the motor outflow at both spinal and supraspinal levels.

Spinal components of the reflex are most influential during the storage phase of the micturition cycle, when sympathetic and somatic motor effects predominate. When the bladder is full, its distension triggers a sensory signal sufficient to activate the pontine micturition center. Parasympathetic mechanisms then predominate to empty the bladder. Somatic control of the external urinary sphincter, which consists of striated muscle, contributes to both phases of the micturition cycle and is a voluntary behavior that originates through forebrain mechanisms (Figure 47–7). Patients with spinal cord injuries at the cervical or thoracic levels retain the reflex but not voluntary control of urination because the connections between the bladder and the pons are severed.

Baroreceptor Reflex

The baroreceptor reflex is one of the simplest mechanisms for regulating blood pressure and an example of homeostatic control by antagonist sympathetic and parasympathetic pathways. It prevents orthostatic hypotension and fainting by compensating for rapid hydrostatic effects produced by changes in posture.

When a recumbent person stands up, the sudden elevation of the head above the heart causes a transient decrease of cerebral blood pressure that is rapidly sensed by baroreceptors in the carotid sinus in

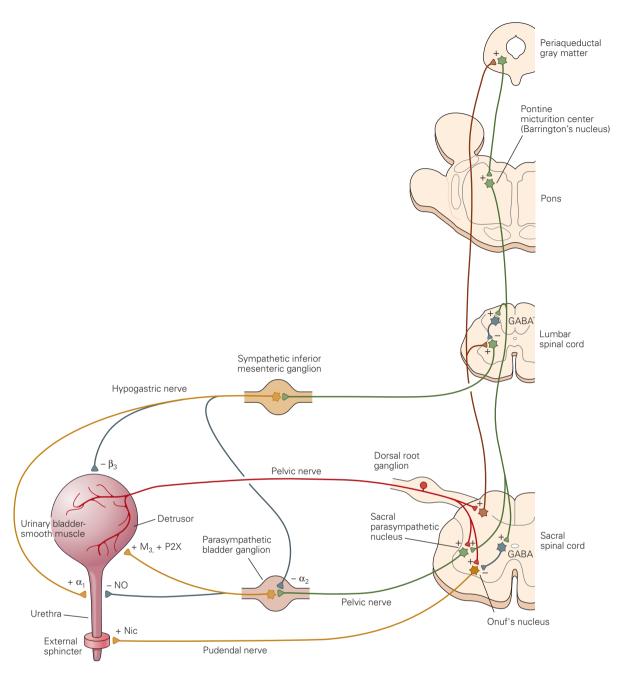

Figure 47-7 The micturition reflex requires interplay between the parasympathetic and sympathetic divisions of the autonomic system. When bladder volume is low, urinary outflow is inhibited because activity in sympathetic pathway is greater than activity in parasympathetic pathway. Mild distension of the detrusor (storage portion of the bladder) initiates a low level of sensory activity, which reflexively activates spinal preganglionic neurons. The resulting low level of preganglionic activity is effectively transmitted and amplified by the sympathetic inferior mesenteric ganglion but filtered out by the parasympathetic bladder ganglion because of differences in patterns of synaptic convergence in the two ganglia. The resulting predominance of sympathetic tone keeps the detrusor relaxed and the urethra constricted. Sympathetic postganglionic fibers also reduce parasympathetic activity by inhibiting preganglionic release of acetylcholine. In addition to their effects on the autonomic outflow, the sensory signals are sufficient to keep the external urinary sphincter closed.

When filling causes the bladder to reach a critical volume, the associated increase in sensory activity reaches a threshold that allows for impulses to pass through the pontine micturition center (Barrington's nucleus). Descending activity from this nucleus then further excites the parasympathetic outflow. The resulting increase in parasympathetic preganglionic firing promotes summation of fast EPSPs and initiation of postsynaptic action potentials in the bladder ganglion as it switches to its "on" state. During the emptying process descending pathways also inhibit the sympathetic and somatic outflows through inhibitory spinal interneurons. Inhibition of somatic motor neurons in Onuf's nucleus causes relaxation and opening of the external sphincter. In this figure the sacral spinal cord is enlarged relative to the other slices. (GABA, γ-aminobutyric acid; NO, nitric oxide; M3, muscarinic ACh receptor 3; nic, nicotinic receptor; P2X, purinergic receptor.) (Adapted, with permission, from DeGroat et al. 1993.)

the neck. Other important pressure sensors are located in the aortic arch and in the pulmonary circulation. When neurons in the ventrolateral medulla detect the decrease in afferent baroreceptor activity produced by low blood pressure, they produce a reflexive suppression of parasympathetic activity and stimulation of sympathetic activity. These changes in autonomic tone restore blood pressure by increasing heart rate, the strength of cardiac contractions, and the overall vascular resistance to blood flow through arterial vasoconstriction.

Under the converse condition of elevated arterial pressure, the increase in baroreceptor activity enhances parasympathetic inhibition of the heart and decreases sympathetic stimulation of cardiac function and vascular resistance. In general, the parasympathetic component of the baroreceptor reflex has a more rapid onset and is briefer than the sympathetic component. Consequently, parasympathetic activity is critical for the rapid response of baroreceptor reflexes but less important than sympathetic activity for long-term blood pressure regulation.

Homeostatic control of physiological functions such as blood pressure and body temperature often involves negative feedback loops. In the baroreceptor reflex, for example, the firing of sensory neurons conveys information about arterial pressure that medullary circuits use as feedback to control descending commands and thereby regulate preganglionic sympathetic neurons. This feedback is said to be negative because of the inverse relation between sensory input and functional motor output: An increase in blood pressure increases sensory activity that decreases sympathetic motor tone, which then reduces pressure.

Set point and gain are critical components of this type of control, as they are in regulating motivational state. The set point is the target for regulation and is analogous to thermostat settings on home heating systems. Gain, as we will see in Chapter 49, is the amplification generated by the feedback loop. The mathematics of control theory shows that the accuracy and speed of regulation through negative feedback are established by the gain of the loop. At a higher gain the reflex loop will control pressure more effectively and more quickly (Figure 47-8B). The overall gain of the baroreceptor reflex is regulated by cellular mechanisms in the sensory transduction process, in the medulla, in paravertebral sympathetic ganglia where integration of nicotinic EPSPs can produce activitydependent gain, and at the neurovascular junctions where co-release of neuropeptide Y can potentiate the actions of norepinephrine on arteries.

Autonomic and Endocrine Function Is Coordinated by a Central Autonomic Network Centered in the Hypothalamus

Sympathetic and parasympathetic response are coordinated by a central autonomic network, a network of brain regions that interacts with two other brain systems to support homeostasis, the "fight-or-flight" response, and reproduction. These other two systems control endocrine responses, especially from the pituitary gland, and the expression of eating and drinking behavior and defensive and reproductive (sexual and parental) behaviors common to all animals. Like the central autonomic network, these two systems are widely distributed in the brain, and their critical control elements are centered in the hypothalamus.

General visceral sensory information reaches the central autonomic network mainly through two cranial nerves (IX and X), which end in the nucleus of the solitary tract, and through the abdominal splanchnic nerves, which end in the spinal cord (see Chapter 45). Splanchnic information is transmitted to the brain through the spinothalamic tract (see Chapter 22), which branches out along the way to several parts of the central autonomic network, including the nucleus of the solitary tract (Figure 47–9A).

The nucleus of the solitary tract has two basic functions. First, it projects to networks in the brain stem and spinal cord that control and coordinate autonomic reflexes. For example, visceral sensory signals relayed through the nucleus regulate vagal motor control of the heart and gastrointestinal tract directly. Some neurons in the nucleus project to neurons in the ventrolateral medullary reticular formation that control blood pressure by regulating blood flow in particular vascular beds differentially (Figure 47–9B). Second, the nucleus has ascending projections that integrate autonomic with neuroendocrine and behavioral responses. As we will see, the forebrain plays an important role in this higher-order coordination.

The nucleus of the solitary tract has direct and indirect projections to the forebrain. A major indirect target is the pontine *parabrachial nucleus*, which is important for behavioral responses to visceral information as well as taste. Lesions of the nucleus prevent behavioral conditioning with gustatory stimuli. The general pattern of ascending projections from the nucleus is remarkably similar to that from the nucleus of the solitary tract. Furthermore, both nuclei receive inputs from many central autonomic centers in the forebrain.

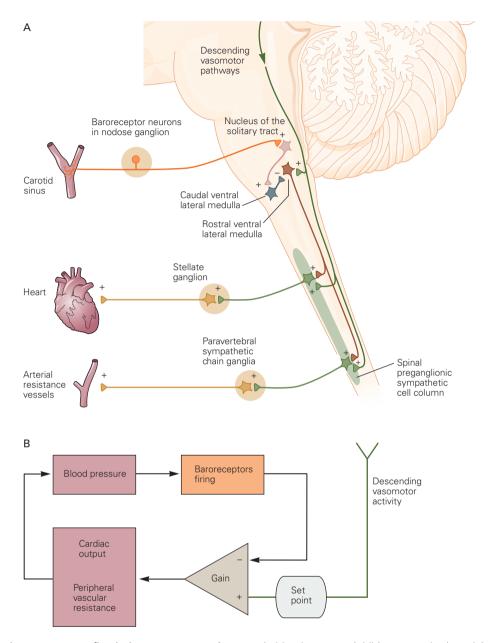

Figure 47–8 The baroreceptor reflex behaves as a negative feedback loop with gain.

A. Arterial blood pressure is sensed by baroreceptors, a type of stretch receptor neuron, in the carotid sinus near the base of the brain. After integration in the medulla this information provides negative feedback control of the cardiovascular system. The sympathetic component of the circuit includes outputs that stimulate the heart's pumping capacity (cardiac output) by increasing heart rate and the strength of contractions. In addition, sympathetic stimulation causes arteries to contract, which raises the hydraulic resistance to blood flow. Together the effects of increased cardiac output and increased vascular resistance raise mean arterial blood pressure. Importantly, inhibitory projections from the caudal to the rostral ventral lateral medulla create negative feedback so that an increase

in blood pressure inhibits sympathetic activity, whereas a decrease raises sympathetic activity. Although omitted for simplicity, parasympathetic neurons in the cardiac ganglion also contribute to the reflex by creating an inhibitory cardiac input that is functionally antagonistic to the sympathetic pathway (see Figure 49–9B). During baroreceptor reflexes parasympathetic activity within the heart is therefore increased by hypertension and reduced by hypotension.

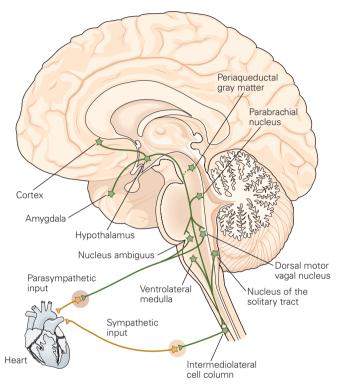

B. The neurons mediating the baroreceptor reflex behave as a negative feedback loop with gain. By amplifying the activity that provides the signals for cardiovascular control, neurons in this circuit can accurately control blood pressure. In a healthy individual with reflex gain of 8, systemic blood pressure can be maintained within 10% of its set point.

A Afferent pathways Periaqueductal gray matter Parabrachial nucleus Cortex Amygdala Hypothalamus Nucleus ambiguus Dorsal motor Ventrolateral vagal nucleus medulla Nucleus of the solitary tract Gut 3

Figure 47–9 The central autonomic network. Nearly all of the cell groups illustrated here are interconnected with one another, forming the central autonomic network.

A. Main afferent pathways. Visceral information (solid lines) is distributed to the brain from the nucleus of the solitary tract and from ascending spinal pathways activated by the splanchnic nerves (from the gut, for example). The nucleus of the solitary tract distributes this information to preganglionic parasympathetic neurons (the dorsal motor vagal nucleus and nucleus ambiguus), to regions of the ventrolateral medulla that coordinate autonomic and respiratory reflexes, and to more rostral parts of the central autonomic network in the pons (parabrachial nucleus), midbrain (periaqueductal gray), and forebrain. The parabrachial nucleus also projects to many of the more rostral components of the central autonomic network, including visceral and gustatory nuclei of the thalamus (dashed lines). Other pathways from the spinal cord (not shown) also transmit

B Efferent pathways

visceral information to many parts of the central autonomic network, including the nucleus of the solitary tract, parabrachial nucleus, periaqueductal gray, hypothalamus, amygdala, and cortex. The spinal cord also projects to the main somatosensory nucleus of the thalamus (ventral posterolateral nucleus).

B. Main efferent pathways. All of the pathways shown here (except perhaps for the periaqueductal gray) project directly to autonomic preganglionic neurons. In the hypothalamus the descending division of the paraventricular nucleus and three cell clusters in the lateral zone project heavily to both parasympathetic and sympathetic preganglionic neurons. Other pathways (not shown) arise from certain monoaminergic cell groups in the brain stem, including noradrenergic neurons in the A5 region and serotonergic neurons in the raphe nuclei.

The periaqueductal gray, surrounds the cerebral aqueduct in the midbrain, which also receives inputs from most parts of the central autonomic network and projects to the medullary reticular formation to initiate integrated behavioral and autonomic responses. For example, in the defensive "fight-or-flight" response the periaqueductal gray helps redirect blood flow from the digestive system to the hind limbs, thus enhancing running.

Viscerosensory and gustatory information is relayed from the nucleus of the solitary tract and parabrachial nucleus in axons that end topographically in a specialized part of the thalamus, the parvicellular (small-cell) part of the ventral posterior nucleus. The parvicellular projections to viscerosensory and gustatory areas in the rostral half of the insular cortex relay information related to hunger, abdominal fullness, dry throat, and holding your breath. Information from the

splanchnic nerves is transmitted to the main part of the ventral posterior nucleus, which receives somatosensory information (see Chapter 22).

The medial prefrontal region of the cerebral cortex is a visceral sensory-motor region. It includes two functional areas that interact with each other: the rostral insular cortex and the rostromedial tip of the cingulate gyrus (also referred to as the infralimbic and prelimbic areas). Stimulation here can produce a variety of autonomic effects including contractions of the stomach and changes in blood pressure. These visceral sensory and motor areas of cortex send descending projections to the parts of the central autonomic network in the brain stem already discussed. Lesions here may produce loss of visceral sensations and taste, as well as a condition known as abulia, where patients show blunted emotional responses to external stimuli.

Finally, visceral regions of cortex, along with many subcortical parts of the central autonomic network, interact with the amygdala. Complex pathways between certain amygdalar cell groups underlie conditioned emotional responses—learned associations between specific stimuli and behaviors with accompanying autonomic responses. When a rat learns that a mild electric shock follows an auditory cue, the auditory cue alone produces an elevated heart rate and the freezing reaction originally elicited by the shock alone (see Chapter 48). Such learned responses are prevented by selective lesions of the amygdalar region, which projects to the hypothalamus and lower brain stem parts of the central autonomic network (including the motor nucleus of the vagus nerve).

The Hypothalamus Integrates Autonomic, Endocrine, and Behavioral Responses

Transection of the brain axis roughly between the midbrain and diencephalon (hypothalamus), without lesioning the hypothalamus, eliminates all spontaneous behavior. In contrast, removal of the entire cerebral hemisphere (cortex and basal nuclei) and thalamus, sparing the hypothalamus, leaves animals able to eat and drink enough to maintain body weight and blood pressure, bear offspring (females only), defend against environmental threats with coordinated behavioral responses, and maintain a constant body temperature. The only difference in the two procedures is whether or not the hypothalamus is left intact (Figure 47–10). The functions of the hypothalamus (Table 47–2) can be enhanced or eliminated when particular sites are experimentally manipulated.

Magnocellular Neuroendocrine Neurons Control the Pituitary Gland Directly

Large neurons in the paraventricular and supraoptic nuclei (and a few neurons scattered in between) form the magnocellular component of the neuroendocrine motor system of the hypothalamus (Figure 47–11). The magnocellular neurons send their axons through the hypothalamo-hypophysial tract to the posterior pituitary or *neurohypophysis* (Figure 47–12). Under normal conditions approximately one-half of the magnocellular neuroendocrine neurons synthesize and secrete vasopressin (the antidiuretic hormone) into the general circulation, whereas the other half synthesize and secrete the structurally similar hormone oxytocin (Figure 47–11). These hormones circulate to organs that control blood pressure, water balance, uterine smooth muscle, and milk release.

In the 1950s Vincent DuVigneaud discovered that vasopressin and oxytocin are peptide hormones, each containing nine amino acid residues (Table 47–3). We later learned that, like other peptide hormones, they are synthesized in the cell body as larger prohormones (see Chapter 13) and then cleaved within Golgi transport vesicles before traveling down the axon to release sites in the posterior pituitary. The genes for these peptides are similar and probably arose by duplication.

Parvicellular Neuroendocrine Neurons Control the Pituitary Gland Indirectly

In the 1950s Geoffrey Harris proposed that the anterior pituitary or *adenohypophysis* is regulated indirectly by the hypothalamus. He showed that the hypophysial portal veins, which carry blood from the hypothalamic median eminence to the anterior pituitary, transport signals released from hypothalamic neurons that control anterior pituitary hormone secretion (Figure 47–12).

In the 1970s Andrew Schally, Roger Guillemin, and Wylie Vale determined the structure of a group of hypothalamic peptide hormones that control pituitary hormone secretion from five classic endocrine cell types in the anterior pituitary. These hormones fall into two classes: releasing hormones and release-inhibiting hormones (Table 47–4). Only one anterior pituitary hormone, prolactin, is under predominantly inhibitory control. Thus transection of the pituitary stalk increases prolactin secretion but causes insufficiency of adrenal cortical, thyroid, gonadal, and growth hormones.

The parvicellular neuroendocrine motor zone is centered along the wall of the third ventricle (Figure 47–10A). One population of parvicellular neurons releases

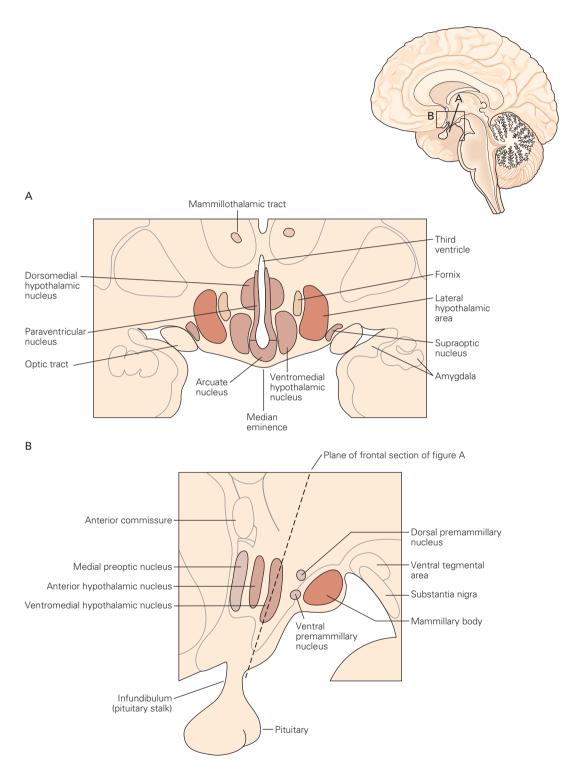

Figure 47–10 The structure of the hypothalamus.

A. Frontal view of the hypothalamus (section along plane A shown in the sagittal view of the brain, upper right). The third ventricle is in the midline; the paraventricular, dorsomedial, and arcuate nuclei adjacent to the ventricle form the neuroendocrine motor zone and periventricular region at this level. The ventromedial nucleus is part of the medial column of hypotha-

lamic nuclei, and the lateral hypothalamic area is the lateral zone component represented in the part of the hypothalamus shown here.

B. Sagittal (rostrocaudal) view of the medial column of hypothalamic nuclei, showing the adjacent (caudal) substantia nigra and ventral tegmental area of the midbrain. The functional significance of key hypothalamic nuclei is summarized in Table 47–2.

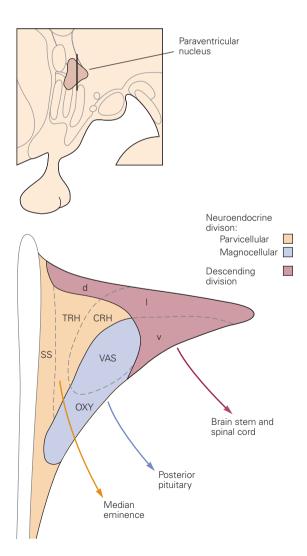

Table 47–2 The Hypothalamus Integrates Behavioral (Somatomotor), Autonomic, and Neuroendocrine Responses Involved in Six Vital Functions

- 1. *Blood pressure and electrolyte composition*. The hypothalamus regulates thirst, salt appetite, and drinking behavior, autonomic control of vasomotor tone, and the release of hormones like vasopressin (via the paraventricular nucleus).
- 2. *Energy metabolism*. The hypothalamus regulates hunger and feeding behavior, the autonomic control of digestion, and the release of hormones such as glucocorticoids, growth hormone, and thyroid-stimulating hormone (via the arcuate and paraventricular nuclei and the lateral hypothalamic area).
- 3. *Reproductive (sexual and parental) behaviors.* The hypothalamus controls autonomic modulation of the reproductive organs and endocrine regulation of the gonads (via the medial preoptic, ventromedial, and ventral premammillary nuclei).
- 4. *Body temperature*. The hypothalamus influences thermoregulatory behavior (seeking a warmer or cooler environment), controls autonomic body heat conservation/loss mechanisms, and controls secretion of hormones that influence metabolic rate (via the preoptic region).
- 5. *Defensive behavior*. The hypothalamus regulates the stress response and fight-or-flight response to threats in the environment such as predators (via the paraventricular, anterior hypothalamic, and dorsal premammillary nuclei, and the lateral hypothalamic area).
- 6. *Sleep-wake cycle*. The hypothalamus regulates the sleep-wake cycle (via a circadian clock in the suprachiasmatic nucleus) and levels of arousal when awake (via the lateral hypothalamic area and tuberomammillary nucleus).

Figure 47–11 The paraventricular nucleus in the hypothalamus is a microcosm of neuroendocrine, autonomic, and sensory-motor integration. The three structural-functional divisions of the paraventricular nucleus are shown. The magnocellular neuroendocrine division comprises two distinct although partly interdigitated pools of neurons. These neurons normally synthesize vasopressin (VAS) and oxytocin (OXY) and release them from axons that course through the internal zone of the median eminence and terminate in the posterior pituitary. Another population of magnocellular neuroendocrine neurons lies in the supraoptic nucleus along the base of the brain.

The parvicellular neuroendocrine division includes three major, separate (although partly interdigitated) pools of neurons. Somatostatin (SS) neurons are concentrated along the wall of the third ventricle; thyrotropin-releasing hormone (TRH) neurons are concentrated a bit more laterally; and corticotropin-releasing hormone (CRH) neurons are concentrated even more laterally. Their axons end in the external zone of the median eminence, where they release their peptide neurotransmitters into the hypophysial portal veins to control anterior pituitary hormone secretion.

The descending division has three parts (dorsal, lateral, and ventral) with topographically organized projections to the brain stem and spinal cord. Axons terminate in many parts of the central autonomic network in the brain stem (see Figure 47-9), the marginal zone (lamina I) of the spinal cord and spinal trigeminal nucleus, and a number of regions in the brain stem reticular formation and periaqueductal gray matter. The descending division modulates autonomic outflow (and inflow), the inflow of nociceptive information, and eating and drinking behaviors. Appropriate integration of magnocellular neuroendocrine, parvicellular neuroendocrine, autonomic, and behavioral responses is mediated primarily by external inputs rather than by interneurons or extensive recurrent axon collaterals of projection neurons. All carefully studied inputs diverge to more than one functional division of the paraventricular nucleus, thus terminating on multiple types of neurons in the nucleus. Circulating steroid and thyroid hormones also produce selective effects on particular types of neurons in the paraventricular nucleus.

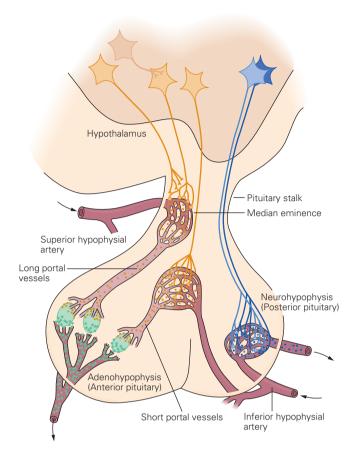

Figure 47–12 The hypothalamus controls the pituitary gland both directly and indirectly through hormone-releasing neurons. Neurons in the magnocellular neuroendocrine system (blue) send their axons directly to the posterior pituitary (neurohypophysis) where they release the peptides vasopressin and oxytocin into the general circulation. Neurons in the parvicellular neuroendocrine system (yellow) send their axons to a venous portal system in the median eminence and pituitary stalk. Long and short portal veins transport hypothalamic hormones (peptides and dopamine) to the anterior pituitary (adenohypophysis) where they bind to five classic types of endocrine cells and influence the release of their hormones (see Figure 47–11). The output of neuroendocrine neurons is regulated in large part by inputs from other regions of the brain. (Reproduced, with permission, from Reichlin 1978; and Gay 1972.)

GnRH. During embryogenesis these neurons arise in a specialized region of the olfactory placode or epithelium and then migrate along the terminal nerves to enter the base of the brain and eventually surround the rostral end of the third ventricle. Remarkably, only about a thousand GnRH neurons control all aspects of reproductive physiology and behavior.

Most of the remaining parvicellular neuroendocrine neurons are exceptionally important for the regulation of metabolism. This population lies within the paraventricular and arcuate nuclei and the short periventricular region between them (Figures 47–10 and 47–12). Distinct pools of neurons release corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), or somatostatin (or growth hormone release-inhibiting hormone). The pool of CRH neurons in the paraventricular nucleus controls the release of anterior pituitary adrenocorticotropic hormone (ACTH), which in turn controls the release of cortisol (glucocorticoids) from the adrenal cortex. Thus this pool of CRH neurons is the "final common pathway" for all centrally mediated stress responses.

The arcuate nucleus contains two critical pools of parvicellular neuroendocrine neurons. One group releases growth hormone-releasing hormone (GRH) and the other dopamine, which inhibits prolactin secretion. Some of the dopaminergic neurons are distributed dorsally as far as the paraventricular nucleus.

The axons of all these parvicellular neuroendocrine neurons travel in the hypothalamo-hypophysial tract and end in the specialized proximal end of the pituitary stalk, the median eminence (Figure 47–12). There, in a region of fenestrated capillary loops in the external zone of the median eminence, the axon terminals release the various hypophysiotrophic factors. The capillary loops are the proximal end of the hypophysial portal system of veins that carry the factors to the anterior pituitary, where they act on cognate receptors on the five types of endocrine cells (Figure 47–11).

Table 47–3 Hormones of the Posterior Pituitary Gland

Name	Structure	Function
Vasopressin	H-Cys-Tyr-Phe-Gln-Asn-Cys-Pro-Arg-Gly- NH ₂ -S-S	Vasoconstriction, water resorption by the kidney
Oxytocin	H-Cys-Tyr-Ile-Glu-Asn-Cys-Pro-Leu-Gly-NH ₂ -S-S	Uterine contraction and milk ejection

Table 47-4 Hypothalamic Substances That Release or Inhibit the Release of Anterior Pituitary Hormones

Hypothalamic substance	Anterior pituitary hormone	
Releasing:		
Thyrotropin-releasing hormone (TRH)	Thyrotropin (TSH), prolactin (PRL)	
Corticotropin-releasing hormone (CRH)	Adrenocorticotropin (ACTH), β-lipotropin	
Gonadotropin-releasing hormone (GnRH)	Luteinizing hormone (LH), follicle-stimulating hormone (FSH)	
Growth hormone-releasing hormone (GHRH or GRH)	Growth hormone (GH)	
Inhibiting:		
Prolactin release-inhibiting hormone (PIH), dopamine	Prolactin	
Growth hormone release-inhibiting hormone (GIH or GHRIH; somatostatin)	Growth hormone, thyrotropin	

An Overall View

The three divisions of the autonomic nervous system form an integrated motor system that acts in parallel with the somatic and neuroendocrine motor systems to maintain homeostasis. Although once viewed as a system that exerts a diffuse control over its targets, recent work has made clear that autonomic neurons are exquisitely specialized to control different targets and that during different behaviors functional subsets of autonomic neurons can be selectively activated.

Synaptic convergence and co-transmission allow autonomic ganglia to operate in different modes: as relays, filters, or amplifiers of preganglionic activity. Even the simplest reflexes in the gut, bladder, or cardiovascular system involve the integration of sensory information and coordination of antagonistic functions.

Visceral sensory afferents are important regulators of motor outflow, and the nucleus of the solitary tract in the medulla is the most important relay station for this sensory information to reach the rest of the central autonomic control network. The hypothalamus integrates autonomic, neuroendocrine, and somatic behavioral responses, which are modulated by inputs from virtually all parts of the nervous system.

Looking back over the past 100 years, autonomic neuroscience has been very influential in shaping general concepts of synaptic transmission—from the first discoveries of neurotransmitters to the first discoveries of co-transmitters—while also having broad impact in the field of medicine. Many of the most commonly prescribed drugs act on the autonomic system and its target tissues.

In this present time of aging populations it is also important to note that many of the physical signs and symptoms associated with old age are autonomic in origin. Think how many people are affected by cardiovascular disease, metabolic and digestive disease, and problems with urogenital function.

One very exciting challenge for the future will therefore be to understand in greater detail how the central autonomic network can be manipulated therapeutically to counteract the loss of peripheral autonomic function. This will require closer interaction between the communities of scientists who study peripheral and central autonomic mechanisms. A second exciting challenge will be to unravel the still mysterious links between motivation, emotion, autonomic function, stress, and neuropsychiatric disorders. By combining current advances in molecular biology, genetics, and computational modeling, meeting all of these challenges now seems possible.

The Neural Correlates of Feeling Are Beginning to Be Understood

An Overall View

LATION, COMPASSION, SADNESS, FEAR, and anger are examples of emotions. These states have an enormous impact on our behavior. But what exactly is an emotion? Unfortunately, the term *emotion* is commonly and confusingly used in two ways. Sometimes it refers to physiological responses to certain kinds of stimuli; when in danger, your muscles tense and your heart pounds, and you may also feel afraid. But it also refers to conscious experiences, called *feelings*, that often (but not always) accompany these bodily responses. We need to consistently distinguish between these two states.

In this chapter we use the term *emotion* to refer to the first of the two states: The set of physiological responses that occur more or less unconsciously when the brain detects certain challenging situations. These automatic physiological responses occur within both the brain and the body proper. In the brain they involve changes in arousal levels and in cognitive functions such as attention, memory processing, and decision strategy. In the body proper they involve endocrine, autonomic, and musculoskeletal responses (see Chapter 47). We use the term *feeling* to refer to the conscious experience of these somatic and cognitive changes. In a certain sense feelings are accounts our brain creates to represent the physiological phenomena generated by the emotional state.

In sum, emotions are automatic, largely unconscious behavioral and cognitive responses triggered when the brain detects a positively or negatively charged significant stimulus. Feelings are the conscious perceptions of emotional responses.

Emotional reactions have been conserved throughout the evolution of species. Behavioral responses that we typically call emotional responses are found in very simple organisms that may not have consciousness and thus not have feelings. A bacterial cell can detect harmful and useful chemicals and respond to these in adaptive ways. Indeed, all organisms must have such capacities to survive and thrive.

Some stimuli—objects, animals, or situations—trigger emotions automatically, even in the absence of experience. These stimuli are said to have *emotional competence*. In addition, some otherwise insignificant objects and events that occur in conjunction with

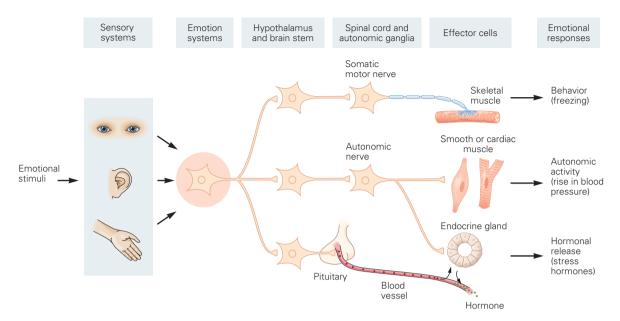

Figure 48–1 Neural control of emotional responses to external stimuli. External stimuli processed by sensory systems converge on emotional processing systems. If the stimuli are emotionally salient, emotion systems such as the amygdala are activated. Outputs of the emotion processing systems to

hypothalamic and brain stem regions activate effector cells that control the expression of physiological responses, including skeletomuscular action, autonomic nervous system activity, and hormonal release. The figure shows some responses associated with fear.

emotionally competent stimuli can acquire emotional significance through associative learning. Thus, whereas emotionally competent stimuli are naturally significant (eg, painful or delicious), other objects and events acquire emotional competence by their association with emotionally competent stimuli.

When the brain detects emotionally competent stimuli, it sends commands to networks that control the endocrine glands, the autonomic motor system, and the musculoskeletal system (Figure 48–1). The endocrine system is responsible for the secretion and regulation of hormones into the bloodstream that affect bodily tissues and the brain. The autonomic system mediates changes in the physiological control systems of the body, including the cardiovascular system and the visceral organs and tissues in the body cavity (see Chapter 47). The skeletal motor system mediates overt behaviors such as freezing, fight-or-flight, and particular facial expressions. Together these three systems control the physiological expression of emotional states.

The autonomic and endocrine changes involved in emotional states are part of the body's homeostatic regulatory mechanisms, which are engaged whenever the body is confronted by an intrinsically charged stimulus. In fact, the body's response to strong emotion is not that different from its response to changes in other drive states or alterations in other bodily regulatory processes such as hunger, thirst, sex, and sleep, or its response to pain or changes in body metabolism that occur during vigorous exercise. These regulatory mechanisms are mediated mostly by subcortical structures—the amygdala, striatum, hypothalamus, and brain stem (see Chapter 47).

Most emotional states are observable either directly (for example, in facial expressions or other overt behaviors) or indirectly with psychophysiological or neurophysiological tests or endocrine assays. Thus many emotional responses are measurable and their neurobiological underpinnings can be investigated objectively in both human beings and experimental animals. On the other hand, measuring subjective feelings is more of a challenge and is only practical in humans.

We begin the chapter with a discussion of the historical antecedents of modern neural science research on emotion. We then describe the neural circuits and cellular mechanisms that underlie the most thoroughly studied emotion, fear. Finally, we consider how the brain processes complex social emotions and conscious feelings.

The Modern Search for the Emotional Brain Began in the Late 19th Century

The modern attempt to understand emotions began in 1890 when William James, the founder of American psychology, asked: What is the nature of fear? Do we run from the bear because we are afraid, or are we afraid because we run? James proposed that the conscious feeling of fear is a consequence of emotions, of the bodily changes that occur during the act of running away—we are afraid because we run.

According to James, each feeling (fear, joy, anger) results from its own unique pattern of emotional expression, or bodily signature, controlled by descending connections from the cerebral cortex. A feeling comes about when the bodily expression of that emotional response enters consciousness. James's peripheral feedback theory drew on the knowledge of the brain at the time, namely, that the cortex had areas devoted to movement and sensation (Figure 48–2). Little was known about specific areas of the brain responsible for emotion and feeling.

At the turn of the 20th century researchers found that animals were still capable of emotional responses after the total removal of the cerebral hemispheres, suggesting that some aspects of emotion are mediated by subcortical regions. The fact that electrical stimulation of the hypothalamus could elicit autonomic responses similar to those that occur as emotional responses in the intact animal suggested to Walter B. Cannon that the hypothalamus might be a key region in the control of fight-or-flight responses and other emotions.

In the 1920s Cannon showed that transection of the brain above the level of the hypothalamus (by means of a cut that separates the cortex and thalamus from the hypothalamus and lower brain areas) left an animal that was still capable of showing rage. But a transection below the hypothalamus, leaving only the brain stem and spinal cord, eliminated the coordinated reactions of natural rage. This clearly implicated the hypothalamus in emotional reactions. Cannon called these hypothalamically mediated reactions "sham rage" as they lacked input from cortical areas, which he assumed were critical for the emotional experience (Figure 48–3).

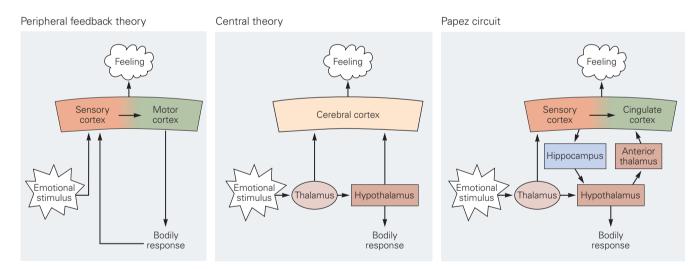

Figure 48–2 Early theories of the emotional brain. (Adapted, with permission, from LeDoux 1996.)

William James's peripheral feedback theory. James proposed that emotionally competent stimuli processed in sensory systems are transmitted to the motor cortex to produce emotional responses in the body. Feedback signals to the cortex convey sensory information about the body responses. The cortical processing of this sensory feedback is the "feeling," according to James.

The Cannon-Bard central theory. Walter Cannon and Philip Bard proposed that emotions are explained by processes within the central nervous system. In their model sensory information

is transmitted to the thalamus where it is then relayed to both the hypothalamus and the cerebral cortex. The hypothalamus evaluates the emotional qualities of the stimulus, and its descending connections to the brain stem and spinal cord give rise to emotional responses. The thalamocortical pathways give rise to conscious feelings.

The Papez circuit. James Papez extended the Cannon-Bard theory by adding additional anatomical specificity. The cortical region that receives hypothalamic output in the creation of feelings is the cingulate cortex. The outputs of the hypothalamus reach the cingulate via the anterior thalamus, and the outputs of the cingulate reach the hypothalamus via the hippocampus.

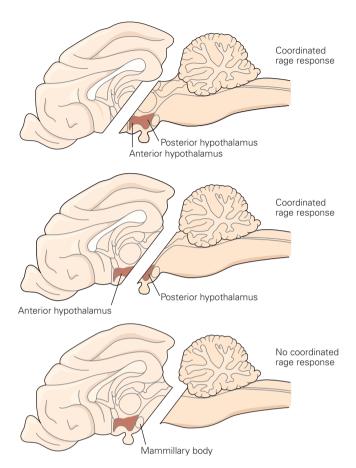

Figure 48–3 Sham rage. An animal exhibits sham rage following transection of the forebrain and the disconnection of everything above the transection (**top**) or transection at the level of the hypothalamus and the disconnection of everything above it (**middle**). Only isolated elements of rage can be elicited if the posterior hypothalamus also is disconnected (**bottom**).

Cannon and his student Phillip Bard proposed an influential theory of emotion centered on the hypothalamus and thalamus. According to their theory, sensory information processed in the thalamus is sent both to the hypothalamus and the cerebral cortex. The projections to the hypothalamus produce emotional responses (through connections to the brain stem and spinal cord) while the projections to the cerebral cortex produce conscious feelings (Figure 48–2). This theory implied that the hypothalamus is responsible for the brain's evaluation of the emotional significance of external stimuli and that emotional reactions depend on this appraisal.

In 1937 James Papez extended the Cannon-Bard theory. Like Cannon and Bard, Papez proposed that

sensory information from the thalamus is sent to the hypothalamus. From there, descending connections to the brain stem and spinal cord give rise to emotional responses and ascending connections to the cerebral cortex give rise to feelings. But Papez expanded the neural circuitry of feelings considerably beyond the Cannon-Bard theory by interposing a new set of structures between the hypothalamus and the cerebral cortex. He argued that signals from the hypothalamus go first to the anterior thalamus and then to the cingulate cortex, where signals from the hypothalamus and sensory cortex converge. This convergence accounts for the conscious experience of feeling. The sensory cortex then projects to both the cingulate cortex and the hippocampus, which in turn makes connections with the mammillary bodies of the hypothalamus, thus completing the loop (Figure 48–2).

In the late 1930s Henrich Klüver and Paul Bucy removed the temporal lobes of monkeys bilaterally and found a variety of psychological disturbances, including alterations in feeding habits (the monkeys put inedible objects in their mouth) and sexual behavior (they attempted to have sex with inappropriate partners, like members of other species). In addition, the monkeys had a striking lack of concern for previously feared objects (eg, humans and snakes). This remarkable set of findings came to be known as the Klüver-Bucy syndrome.

Building on the Cannon-Bard and Papez models, and the findings of Klüver and Bucy, Paul MacLean suggested in 1950 that emotion is the product of the "visceral brain." The visceral brain included the various cortical areas that had long been referred to as the limbic lobe, so named by Paul Broca because these areas form a rim (Latin *limbus*) in the medial wall of the hemispheres. Later the visceral brain was renamed the *limbic system*. The limbic system includes the various cortical areas that make up Broca's limbic lobe (especially medial areas of the temporal and frontal lobes) and the subcortical regions connected with these cortical areas, such as the amgydala and hypothalamus (Figure 48–4).

MacLean intended his theory to be an elaboration of Papez's ideas. Indeed, many areas of MacLean's limbic system are parts of the Papez circuit. However, MacLean did not share Papez's idea that the cingulate cortex was the seat of feelings. Instead he thought of the hippocampus as the part of the brain where the external world (represented in sensory regions of the lateral cortex) converged with the internal world (represented in the medial cortex and hypothalamus), allowing internal signals to give

emotional weight to external stimuli and thereby giving rise to conscious feelings. For MacLean the hippocampus was involved both in the expression of emotional responses in the body and in the conscious experience of feelings.

Subsequent findings raised problems for MacLean's limbic system theory. In 1957 it was found that damage to the hippocampus, the keystone of the limbic system, produced deficits in converting short- to long-term memory, a distinctly cognitive function. In addition, animals with damage to the hippocampus are able to express emotions, and humans with hippocampal lesions express and feel emotions normally. In general,

damage to areas of the limbic system did not have the expected effects on emotional behavior.

Several of MacLean's other ideas on emotion are nevertheless still relevant. MacLean thought that emotional responses are essential for survival and therefore involve relatively primitive circuits that have been conserved in evolution, and this notion is key to an evolutionary perspective of emotion. Further, his idea that emotional states and cognitive processes involve somewhat distinct circuits and can function relatively independent of one another, as implied by Cannon and Bard and all subsequent theories of the emotional brain, also has some merit.

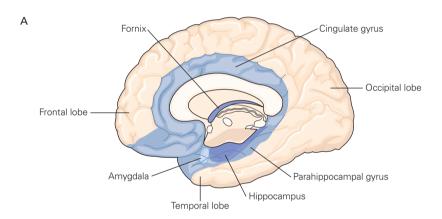

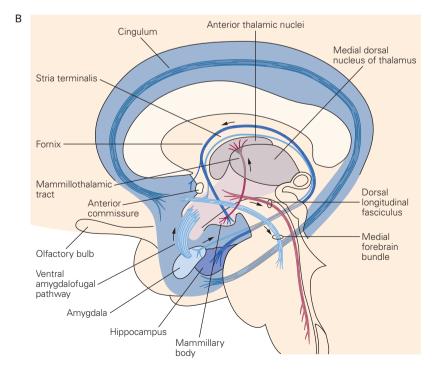

Figure 48–4 The limbic system consists of the limbic lobe and deep-lying structures.

A. This medial view of the brain shows the prefrontal limbic cortex and the limbic lobe. The limbic lobe consists of primitive cortical tissue (blue) that encircles the upper brain stem as well as underlying cortical structures (hippocampus and amygdala).

B. Interconnections of the deep-lying structures included in the limbic system. The arrows indicate the predominant direction of neural activity in each tract, although these tracts are typically bidirectional. (Adapted, with permission, from Nieuwenhuys et al. 1988.)

The Amygdala Emerged as a Critical Regulatory Site in Circuits of Emotions

Although damage to most limbic areas does not have the effects on emotional behavior predicted by the limbic system theory, one limbic area was consistently shown to be involved in emotion. This area is the amygdala.

Studies of Avoidance Conditioning First Implicated the Amygdala in Fear Responses

In the mid-1950s Lawrence Weiskrantz sought to understand which region of the temporal lobe was responsible for the emotional changes characteristic of the Klüver-Bucy syndrome. To do this, he used avoidance conditioning, a form of instrumental conditioning.

In avoidance conditioning an animal learns to perform responses that successfully avoid an aversive shock, the unconditioned stimulus (US). Successful avoidance of shock reinforces the response, ie, it increases the probability of the response. Normal monkeys learn instrumental responses (ie, pressing a lever) to avoid the shock, but monkeys with lesions of the amygdala do not. Weiskrantz concluded that a key function of the amgydala was to connect external stimuli with their aversive (punishing) or rewarding consequences.

Fear has been a popular emotion in neuroscience research because it is so important for survival and also because excellent behavioral protocols are available for studying fear in animals. Following Weiskrantz's discovery, many researchers used avoidance conditioning to study the neural mechanisms of fear. However fear can also be studied using Pavlovian conditioning and by the early 1980s had become the preferred protocol.

Pavlovian Conditioning Is Used Extensively to Study the Contribution of the Amygdala to Learned Fear

In Pavlovian fear conditioning an association is learned between the US (eg, shock) and the conditioned stimuli (CS) that predict the US. For example, an emotionally neutral CS (a tone) is presented for several seconds and the animal is shocked during the final second of the CS. After several pairings of tone and shock, presentation of the tone alone elicits defensive freezing and associated changes in autonomic and endocrine activity. In addition, many defensive reflexes, such as eyeblink and startle, are facilitated by the tone alone.

Pavlovian fear conditioning is actually the first phase of avoidance conditioning. The pairing of US and CS initially results in the conditioning of a response, but in the second phase the animal learns to perform an instrumental response to avoid the shock. By the early 1980s neuroscientists began to realize that a more efficient way to study fear learning is to focus on the first stage of avoidance conditioning—Pavlovian fear conditioning—and not extend the experimental design to the second phase.

Research carried out in a variety of laboratories established that lesions of the amygdala prevent Pavlovian fear conditioning from occurring. Animals with amygdala damage fail to learn the association between the CS and the US and thus do not express fear when the CS is later presented alone.

The amygdala consists of approximately 12 nuclei, but the lateral and central nuclei are especially important in fear conditioning (Figure 48–5). Damage to either nucleus, but not other regions, prevents fear conditioning. The lateral nucleus is the input nucleus receiving information about the CS (eg, a tone) from the thalamus. The central nucleus is the output region; neurons here project to brain stem areas involved in the control of defensive behaviors and associated autonomic and humoral responses (see Chapter 47). The lateral and central nuclei are connected by way of several intra-amygdala circuits, including connections in the basal and intercalated nuclei.

Sensory inputs reach the lateral nucleus from the thalamus both directly and indirectly. Much as predicted by the Cannon-Bard hypothesis, sensory signals from thalamic relay nuclei are conveyed to sensory areas of cortex. As a result the amygdala and cortex are activated simultaneously. However, the amygdala is able to respond to a danger cue before the cortex can process the stimulus information. Given that cortical processing is required to consciously experience fear, the emotional state triggered by thalamic inputs is likely to be initiated before we consciously feel fear.

The lateral nucleus is thought to be a site of synaptic change during fear conditioning. The CS and US signals converge in the lateral nucleus; when the CS and US are paired, the effectiveness of the CS is enhanced (Figure 48-6). The lateral nucleus appears to be functionally divided. Neurons in the most dorsal part of the dorsal division appear to initiate learning when the CS and US are paired, whereas neurons in an adjacent ventral part of the dorsal division are thought to mediate the long-term memory of the CS-US association. Recent studies have also shown that synaptic plasticity occurs in specific central amygdala circuits. The central amygdala thus does not simply drive motor outputs but is also part of the circuitry through which fear associations are formed and stored, very likely by transmitting information about the CS and US from the lateral nucleus.

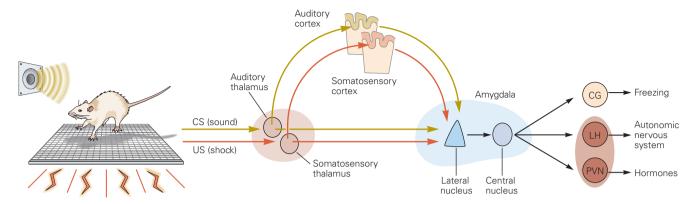

Figure 48–5 Neural circuits engaged during fear conditioning. The conditioned stimulus (CS) and unconditioned stimulus (US) are relayed to the lateral nucleus of the amygdala from the auditory and somatosensory regions of the thalamus and cerebral cortex. Convergence of the CS and US pathways in the lateral nucleus is believed to underlie the synaptic changes that mediate learning (see Figure 48–6). The lateral nucleus communicates with the central nucleus both directly and

through intra-amygdala pathways (not shown) involving the basal and intercalated nuclei. The central nucleus then connects with regions that control various motor responses, including the central gray region (CG), which controls freezing behavior, the lateral hypothalamus (LH), which controls autonomic responses, and the paraventricular hypothalamus (PVN), which controls stress hormone secretion by the pituitary-adrenal axis. (Reproduced, with permission, from Medina et al. 2002.)

The emotional charge of a stimulus is evaluated by the amygdala to determine whether danger is present. If the amygdala detects danger, it orchestrates the expression of behavioral and physiological responses by way of connections to the hypothalamus and brain stem. For example, freezing behavior is mediated by connections from the central nucleus to the ventral periaqueductal gray region. But in addition, the amygdala has a variety of connections that allow it to also influence other cognitive functions. For example, through its widespread projections to cortical areas it can modulate attention, perception, memory, and decision-making. Its connections with the modulatory dopaminergic, noradrenergic, serotonergic, and cholinergic nuclei that project to cortical areas also influence cognitive processing (see Chapter 46).

The cellular and molecular mechanisms within the amygdala that underlie learned fear, especially in the lateral nucleus, have been elucidated in great detail (see Chapter 66). The findings support the view that the lateral nucleus is a site of memory storage in fear conditioning.

The Amygdala Has Been Implicated in Unconditioned (Innate) Fear in Animals

Many animals rely on innate (unconditioned) olfactory signals in the detection of threats, mates, food, and so forth. For example, rodents exhibit freezing and other defensive behaviors when fox urine is detected.

Recent studies have made considerable progress in uncovering the circuits underlying innate fear (see Chapter 47). In mammals unconditioned threats involving predator or conspecific odors are transmitted from the vermonasal component of the olfactory system (see Chapter 32) to medial amygdala. Outputs of the medial amygdala reach the ventromedial hypothalamus, which connects with the premammillary hypothalamic nucleus. In contrast to learned fear, which depends on the ventral periaqueductal gray region, unconditioned fear responses depend on connections from the hypothalamus to the dorsal periaqueductal gray region.

The Amygdala Is Also Important for Fear in Humans

The basic findings in animals regarding the role of the amygdala in emotion have been confirmed in studies of humans. Thus patients with damage to the amygdala fail to undergo fear conditioning when presented with a neutral CS paired with a US (electric shock or loud noise). Patients with damage to the amygdala also fail to recognize facial expressions of fear and do not generate autonomic fear responses to these.

In normal human subjects activity in the amygdala increases during CS–US pairing (Figure 48–7). This activity is especially strong when the stimuli are presented subliminally. In normal subjects fearful facial

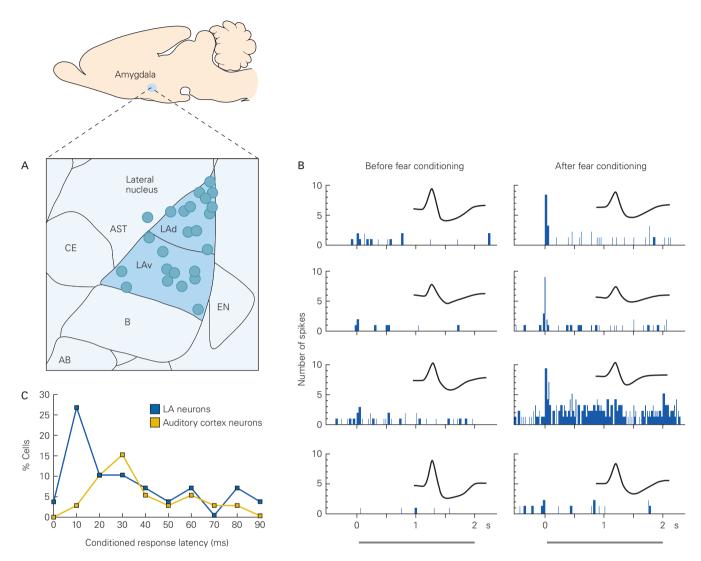

Figure 48–6 The responses of the lateral nucleus of the amygdala are enhanced by fear conditioning.

A. The blue dots indicate the placement of extracellular electrodes in the lateral nucleus. (AST, amygdalo-striatal transition area; AB, accessory basal nucleus of the amygdala; B, basal nucleus of the amygdala; CE, central nucleus of the amygdala; EN, endopiriform cortex; LAd, dorsal lateral nucleus; LAv, ventral lateral nucleus.)

B. Histograms show activity in four simultaneously recorded neurons in the lateral nucleus before and after conditioning. Each histogram represents the sum of 10 presentations of the conditioned stimulus (**black bar**). Representative spike waveforms are shown in insets.

C. After conditioning, the neurons in the dorsal lateral nucleus fire at shorter latencies than do neurons in the auditory cortex. They also fire at higher frequencies (not shown).

expressions also activate the amygdala, even when presented subliminally. These findings emphasize the importance of the amygdala as a subconscious evaluator of the meaning of a stimulus.

Certain forms of fear processing are unique to humans. For example, simply telling a human subject that the CS may be followed by a shock is enough to allow the CS to elicit fear responses. The CS elicits characteristic autonomic responses even though it was never associated with the delivery of the shock. Humans can also be conditioned by allowing them to observe someone else being conditioned—the observer learns to fear the CS even though the CS or US were never directly presented to the observing subject.

The emotional learning and memory capacities of the human amygdala fall into the category of *implicit* learning and memory (unconscious recall of perceptual and motor skills (see Chapter 65)). In situations of danger, however, the hippocampus and other components of the medial temporal lobe system concerned with *explicit learning* and memory (the conscious recall of people, places, and things) will encode the learning such that learned indicators of danger can also be recalled consciously.

Studies of patients with bilateral damage to the amygdala or hippocampus illustrate the separate

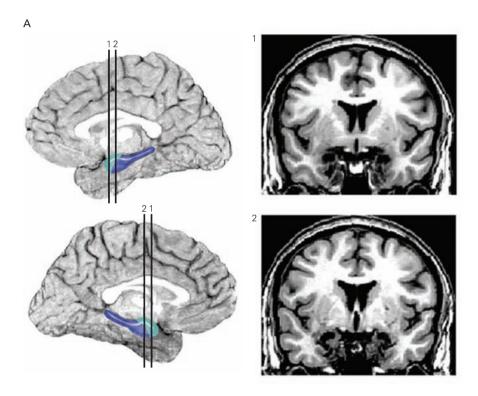

contributions of the amygdala and the hippocampus to implicit and explicit memory, respectively. Patients with damage to the amygdala show no physiological responses to a CS (indicating no implicit learning) but have good memory of the conditioning experience (indicating explicit learning), whereas patients with hippocampal damage respond normally to the CS but have no conscious memory of the conditioning experience.

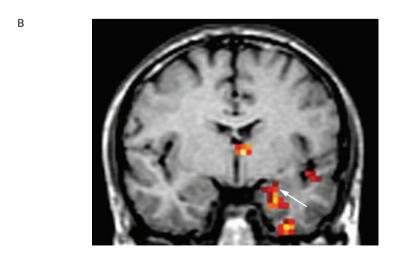

Amygdala function is altered in a number of psychiatric disorders in humans, especially disorders

Figure 48–7 Lesion and imaging results implicate the human amygdala in conditioned fear.

A. Left side: Three-dimensional magnetic resonance imaging (MRI) reconstructions of a normal brain seen from a medial perspective (right hemisphere on top, left hemisphere below). The amygdala (light blue) and the hippocampus (dark blue), normally hidden by the parahippocampal gyrus, were traced and colored. Right side: Two coronal slices through the damaged amygdala of a patient with Urbach-Wiethe disease at the levels shown on the three-dimensional reconstruction. In such patients damage to the amygdala impairs fear responses and blocks fear conditioning. (Reproduced, with permission, from Hanna Damasio and Joel Bruss.)

B. Conditioned fear stimuli activate the human amygdala (arrow). Healthy volunteers underwent fear conditioning while their brains were scanned using functional MRI. Conditioning involved two conditioned stimuli, one paired with the unconditioned stimulus (CS+) and one not (CS-). Selective activation was assessed by subtracting the CS- scans from the CS+ scans. (Adapted, with permission, from LaBar et al. 1998.)

of fear and anxiety (see Chapter 63). In addition, the amygdala plays an important role in processing cues related to addictive drugs (see Chapter 49).

The Amygdala Is Involved in Positive Emotions in Animals and Humans

Although most work on the neural basis of emotion during the last half century has focused on aversive responses, especially fear, other studies have shown that the amygdala is also involved in positive emotions, in particular the processing of rewards. In monkeys and rats the amygdala is required for associating neutral stimuli with rewards.

Studies in nonhuman primates and rodents have followed up on Weiskrantz's suggestion that the amygdala connects stimulus rewards as well as punishers. For example, in a recent study monkeys were trained to associate abstract visual images with a reward or punisher. The meaning was then reversed (eg, by pairing a punisher with a stimulus that had previously been associated with a reward). In this way it was possible to separate the contributions of the amygdala to visual and value processing. Changes in the value of the images modulated neural activity in the amygdala, and the modulation occurred rapidly enough to account for behavioral learning.

A growing number of functional imaging studies of humans have also shown that the amygdala is involved in emotions. For example, the human amgydala is activated when subjects observe pictures of stimuli associated with food, sex, and money, or when people make decisions based on the reward value of stimuli.

Other Brain Areas Contribute to Emotional Processing

In addition to the amygdala, other brain areas make important contributions to emotional processing As seen in the case of conditioned and unconditioned fear, the amygdala contributes to emotional processing as part of a larger circuit that includes regions of the hypothalamus and brain stem, eg, the periaqueductal gray region in the brain stem.

Cortical areas are also important. A number of studies in humans have implicated the ventral region of the anterior cingulate cortex, the insular cortex, and the ventromedial prefrontal cortex in various aspects of emotional processing. These cortical circuits are especially important in complex emotional states.

Complex feelings are associated with social interaction, and range from empathy and pride to embarrassment and guilt. As in the primary emotions such as fear, pleasure, or sadness, social emotions consist of specific bodily changes and behaviors and are experienced consciously as distinct feelings. These feelings make important contributions to normal social interactions.

Studies of patients with neurological disease and focal brain lesions have advanced the understanding of the neural basis of social emotions. For example, damage to some sectors of the prefrontal cortex markedly impairs social emotions and related feelings. In addition, these patients show marked changes in social behavior that resemble the behavior of patients with developmental sociopathic personalities. Patients with damage to some sectors of the prefrontal cortex are unable to hold jobs, cannot maintain stable social relationships, are prone to violate social conventions, and cannot maintain financial independence. It is common for family ties and friendships to break after the onset of this condition. Recent studies reveal that, under controlled experimental conditions, the moral judgments of these patients can be flawed.

Unlike patients with parietal or parieto-frontal damage, patients with frontal damage do not have motor defects such as limb paralysis or speech defects and thus may appear at first to be neurologically normal. Their perceptual abilities, attention, learning, recall, language, and motor abilities do not show signs of disturbance. Some patients have IQ scores in the superior range. For these reasons they return to their work and social activities after their initial recovery from brain damage. Only when they start to interact with others are their defects noticed.

In the prefrontal cortex the ventromedial sector is particularly important. In most patients with impaired social emotions this sector is damaged bilaterally (Figure 48–8), although damage restricted to the right side is sufficient to cause antisocial symptoms. The critical region encompasses Brodmann's areas 12, 11, 10, 25, and 32, which receive extensive projections from the dorsolateral and dorsomedial sectors of the prefrontal cortex. Some of these areas project extensively to subcortical areas related to emotions: the amygdala, hypothalamus, and periaqueductal gray region in the brain stem tegmentum.

Patients with these frontal lesions do not exhibit changes in heart rate or degree of palm sweating when shown stimuli that normally cause emotions, although they can describe flawlessly the pictures. Normal subjects are equally proficient at describing the pictures but also have psychophysiological responses to the pictures. Unlike normal subjects, patients with frontal lesions do not show detectable skin conductance changes, a sign of sympathetic activation, during the

Figure 48–8 Prefrontal lesions can lead to a form of acquired sociopathy. This three-dimensional (MRI) reconstruction of a human brain shows damage centered in the ventral and medial region of the prefrontal cortex in both cerebral hemispheres. Such damage markedly impairs emotional responses, especially in the domain of social emotions and decision making. (Images, reproduced with permission, from Hanna Damasio.)

period that precedes making risky and disadvantageous decisions, suggesting that their emotional memory is not engaged during that critical period. Also unlike normal subjects, these patients fail in tasks in which they have to make a decision under conditions of uncertainty, and in which reward and punishment are important factors.

Interestingly, when asked about punishment, reward, or responsibility, adult patients with prefrontal damage respond as if they still have the basic knowledge of the rules, but their actions indicate that they fail to use them in real situations. This dissociation suggests that their behavioral defects are not caused by a loss of factual knowledge but rather by a difficulty in accessing that knowledge, perhaps because of defective emotional processing.

Functional imaging of normal human subjects shows that the ventromedial frontal cortex is activated during the period before a decision. That same region is activated by tasks involving punishment and reward, supporting the notion that the emotional significance of punishment and reward is relevant for decision making. Punishment and reward are frequently featured in experiments involving economic and moral decisions.

The prefrontal cortex, especially areas in the ventromedial sector, operates in parallel with the amygdala. During an emotional response ventromedial areas govern the attention accorded to certain stimuli, influence the content retrieved from memory, and help shape mental plans conceived as a response to the triggering stimulus. By influencing attention, both the amygdala and the ventromedial prefrontal cortex are also likely to alter cognitive processes, for example by speeding up or slowing down the flow of sensory representations (see Chapter 17). All of these changes are eventually incorporated in the circuitry of working memory in the dorsolateral prefrontal cortex, which contributes to the processing of conscious feelings.

The Neural Correlates of Feeling Are Beginning to Be Understood

We have defined feeling as the conscious experience of an emotion. Thus attempts to study the neural correlates of feelings in experimental animals are difficult because feelings are inherently subjective. Evidence for the neural correlates of feeling comes primarily from functional imaging studies of humans and from neuropsychological testing of patients with specific brain lesions.

One functional imaging study used positron emission tomography (PET) to test the idea that feelings

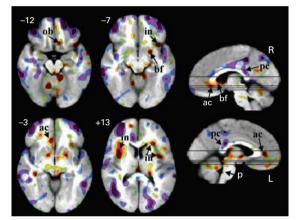

are correlated with activity in cortical and subcortical somatosensory regions that specifically receive inputs related to the internal environment—the viscera, the endocrine glands, and the musculoskeletal system. Normal subjects were asked to recall personal episodes involving four different emotions—sadness, happiness, anger, and fear—and to attempt to reexperience as closely as possible the emotion that accompanied those events. From the moment a subject was told which episode or emotion to reexperience until the end of the scanning, the activity level in a number of cortical and subcortical regions was analyzed continuously,

along with several psychophysiological parameters, such as skin conductance.

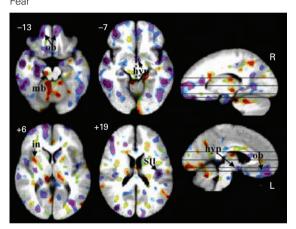

Activity changed in the insular cortex, secondary somatosensory cortex (S-II), cingulate cortex, hypothalamus, and upper brain stem, and the pattern of change differed with each emotion (Figure 48–9). Patterns of activation did not overlap. These results support the idea that at least a part of the neural substrate for feelings corresponds to the changes in the pattern of activity caused by the emotion being elicited.

When, for example, subjects experienced sadness, the subgenual sector of the cingulate cortex was

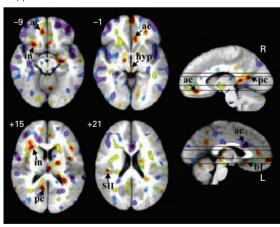

Fear

Happiness

Anger

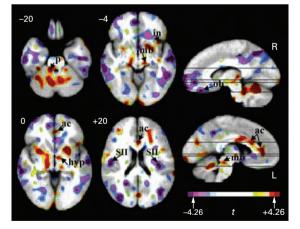

Figure 48–9 Neural correlates of feelings. Subjects were asked to reexperience specific emotions and feelings through autobiographic memories while the brain was scanned using positron emission tomography. The four panels show the brain regions activated or deactivated during different feelings. Significant increases of activity are shown in **orange** and **red**; significant decreases in **blue** and **purple**. The level of activity changes significantly in several brain regions that directly or

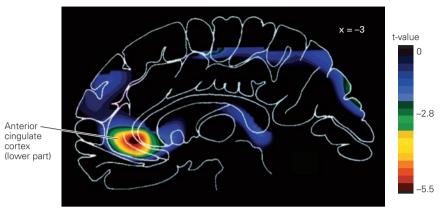

indirectly receive or transmit signals to and from the body. The orbital frontal cortex is also engaged. The patterns of activity differ with each feeling. The results support the hypothesis that feelings are correlated with activity in brain regions concerned with representing and monitoring body states. (in, insular cortex; S-II, secondary somatosensory area; hyp, hypothalamus; ac, anterior cingulate cortex; pc, posterior cingulate cortex; bf, basal forebrain; mb, midbrain; p, pons; ob, orbitofrontal cortex.)

Figure 48–10 Activity in an area of the anterior cingulate cortex is differentially active in patients with depression when they recall sad events. The t-value indicates significance of activity. (In part A red denotes decreased activity, whereas in part B it denotes increased activity.)

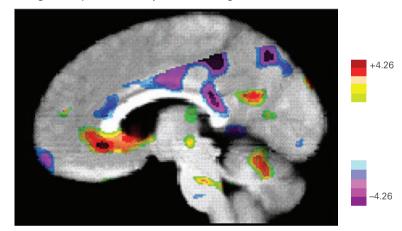

A. In PET scans of patients with depression an area in the lower sector ion the anterior cingulate cortex shows low activity. This area, the subgenual sector, is Brodmann's area 25. In MRI studies of patients with chronic depression the same area is thinned out. (Reproduced, with permission, from Wayne Drevets.)

B. The same sector is intensely active in normal subjects recalling sad events from their own life. Helen Mayberg has found that electrical stimulation of this cortical region in patients with severe and refractory depression relieves the depressive symptoms rapidly and dramatically. (Reproduced, with permission, from Damasio et al. 2000.)

B High activity in normal subjects recollecting sad events

activated. This region is of special interest because it is also differentially activated in patients with bipolar depression. Moreover, this region appears thinned in structural MRI scans of patients with chronic depression (Figure 48–10). The amygdala is not activated during conscious feeling, evidence that it deals mainly with unconscious emotional states.

In humans, sectors of the insular cortex that are activated during recall of feelings are also activated during the conscious sensation of pain and temperature. The insular cortex receives homeostatic information (temperature and pain signals, changes in blood pH, carbon dioxide, and oxygen) through pathways that originate in peripheral nerve fibers. These afferent fibers include, for example, the C and A δ fibers. Those fibers form synapses with neurons in lamina I of the spinal cord's posterior horn or the pars caudalis of the trigeminal nerve nucleus in the brain stem. The pathways from lamina I and the trigeminal nucleus

project to brain stem nuclei (nucleus of the solitary tract and parabrachial nucleus); from there to the thalamus and then to the insular cortex. The identification of this functional system is further support for the idea that signals in the afferent somatosensory pathways play a role in the processing of feelings. Moreover, in patients with pure autonomic failure, a disease in which visceral afferent information is severely compromised, functional imaging studies reveal a blunting of emotional processes and attenuation of activity in the somatosensory areas that contribute to feelings.

Like other feelings, social feelings engage the insular cortices and the primary and secondary somatosensory cortices (S-I and S-II), as has been shown in functional neuroimaging experiments evaluating empathy for pain and, separately, admiration and compassion.

Insights about the neural correlates of feeling also have come from examination of patients with focal

lesions. Damage to the right somatosensory cortex (S-II, S-I, and insula) impairs social feelings such as empathy. Consistent with this finding, patients with lesions in the right somatosensory cortex fail to guess accurately the feelings behind the facial expressions of other individuals. This ability to read faces is not impaired in patients with comparable lesions of the left somatosensory cortex, indicating that the right cerebral hemisphere is dominant in the processing of at least some feelings. Body feelings such as pain and itch remain intact as do feelings of basic emotions such as fear, joy, and sadness.

On the other hand, damage to the human insular cortex, especially on the left, can suspend addictive behaviors, such as smoking. This suggests that the insular cortices play a role in associating external cues with internal states such as pleasure and desire. Interestingly, complete bilateral damage to the human insular cortices, as caused by herpes simplex encephalitis, does not preclude emotional feelings or body feelings, suggesting that the somatosensory cortices and subcortical nuclei in the hypothalamus and brainstem are also involved in generating feeling states.

Finally, the neural basis for the hedonic component or pleasure aspect of feeling states is being elucidated in animal studies by Kent Berridge and his colleagues. These studies consistently implicate the nucleus accumbens and other nuclei of the basal ganglia, especially in the ventral striatum and ventral pallidum. A growing number of functional imaging studies of humans—especially in the field of neuroeconomics, which combines research methods from neuroscience, experimental and behavioral economics, and cognitive and social psychology to explore decision-making in humans—point in the same direction.

An Overall View

In the overall physiology of life regulation emotional states sit between the simple processes of reflexes and homeostatic regulation, on the one hand, and cognitive processes on the other.

Emotions serve as cues to appropriate behavior in response to challenges and opportunities in the environment, allowing an organism to deploy specific advantageous behaviors rapidly. The neural processing responsible for emotional states and their effect on behavior is largely unconscious, much as Freud had predicted. Indeed, functional imaging studies show that the amygdala is readily activated by stimuli that are prevented from entering awareness. But even though the initial neural processing of emotionally

competent stimuli may be unconscious, that process can lead to feelings, the conscious awareness of the brain's response to the stimuli.

What might the adaptive role of feelings be? Given that emotional states can arise automatically and effectively, what would be the advantage of bringing to consciousness the physiological changes that constitute emotions? The observation of brain-damaged patients in whom feelings are severely compromised gives one possible answer: The loss or impairment of the neural processes responsible for feelings diminishes the ability to anticipate and plan behavior.

Conscious feelings facilitate learning about objects and situations that cause emotional responses. Thus feelings enhance the behavioral significance of emotions and orient the imaginative process necessary for planning of future actions. In brief, unconscious emotional states are automatic signals of danger and advantage, whereas conscious feelings, by recruiting cognitive abilities, give us greater adaptability in responding to dangerous and advantageous situations. Indeed, both emotions and feelings also play a major role in social behavior, including the formation of moral judgments and the framing of economic decisions.

An Overall View

THE TEMPERATURE OF THE AIR AT higher latitudes can fluctuate by 70°C (158°F) or more over the year, yet some birds and mammals live year round in such environments without hibernating or estivating. These animals keep their core temperatures within a narrow range, on the order of a few degrees, during both the fierce blizzards of winter and the sultry days of summer. This regulatory feat is just one of many that keep key physiological variables within limits favorable to vital processes of the body, such as cell division, energy metabolism, macromolecular synthesis, and cell signaling.

The active maintenance of a relatively constant internal environment is called *homeostasis*. Constancy of the internal environment is the basis of the freedom of action we and other animals enjoy because it partially decouples our physiology from immediate external conditions and greatly extends the range of available habitats. For example, salmon are able to live in both fresh and salt water because they can regulate the osmolality of their extracellular fluid. Hagfish, conversely, are confined to marine habitats because they cannot regulate the osmolality of their extracellular fluid, which reflects that of the external environment.

In climates with wide variation in temperature the budget-minded homeowner may set the thermostat to a lower value during the winter and a higher one during the summer; more sharply contrasting daytime and nighttime settings may be chosen when heating or air-conditioning costs are high. Similarly, in physiological systems the means and variances of regulated variables may be adjusted over the course of the day, the seasons, and the life cycle. For example,

a dehydrated camel conserves water by letting its temperature increase above normal before beginning to sweat; at night it lets its temperature decrease below normal, thus starting the day cooler and delaying the onset of sweating. The zoologist Nicholas Mrosovsky has coined the term *rheostasis* to refer to the linkage of regulatory targets and ranges to chronobiological and life-cycle events.

Regulation is achieved through interlinked control systems with both physiological and behavioral outputs (Box 49–1). A key feature of these control systems is *motivational states* such as hunger and thirst. These states arise as responses to internal stimuli, such as signals from detectors of core temperature, and external stimuli, such as the sight of a shaded refuge from the sun. Motivational states influence the

Box 49-1 What Is a Regulated System?

A simple regulated system is illustrated in Figure 49–1A. Water pours into a reservoir from a supply pipe and leaks out through a drain pipe. A float provides information about the water level. A shaft links the float to two valves. One controls the inflow through the supply pipe. This

linkage is called *negative feedback* because raising the water level decreases flow through the supply pipe, and the linkage extends back from the float to an upstream stage of the system. The other valve controls outflow through the drain pipe. Such a linkage is called *positive feed-forward*

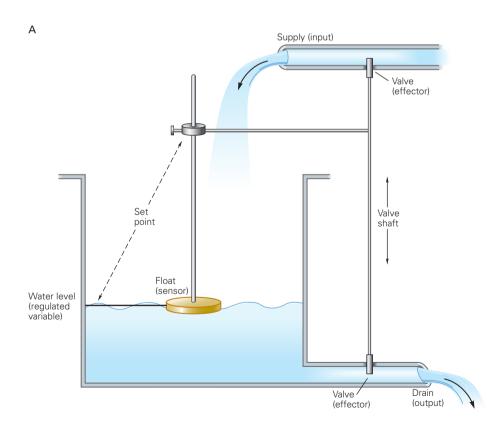

Figure 49–1A A simple regulated system. Changes in the position of the float alter the state of the valves in the supply and drain pipes so as to oppose changes in the

water level. (Adapted, with permission, from Cabanac and Russek 2000.)

direction and vigor of behavior, steering the animal toward regions of the environment where conditions promote maintenance of normal body temperature and where resources essential to homeostasis, such as food and water, can be found. These states also influence the frequency and vigor of nonregulatory activities such as exploration and reproduction.

In this chapter we first look at homeostasis by focusing on the control systems responsible for the regulation of fluid and energy balance. We then explore motivational states, focusing on the brain's reward circuitry. Finally, we examine how motivational states and related homeostatic processes are co-opted by drugs of abuse and result in addictive behavior.

because raising the water level increases flow through the drain pipe, and the linkage extends forward from the float to a downstream stage of the system.

The feedback and feed-forward linkages between the float and the valves regulate the water level. Even if the flow rate in the supply or drain pipe is altered by adding a booster pump or a partial blockage, the valves will compensate, and the water level will be confined to a narrow range. The two valves are called effectors because they bring about the adjustments that regulate the water level.

Physiological regulation is often achieved by means of a combination of negative feedback control over inputs and positive feed-forward control over outputs. For example, to maintain body weight after consuming a large meal, it is useful both to reduce subsequent food intake and to increase energy expenditure.

Figure 49–1B shows a control diagram of the regulated system in Figure 49–1A. The float is called a *sensor*

because it monitors the regulated variable, the water level, within a *regulated compartment*, the reservoir. The output of the sensor is compared to a reference value or *set point*, a water level determined by the height on the float shaft at which the valve shaft is attached. Movement of the waterline away from the set point drives the two effectors to oppose the deviation, thus holding the water level close to the set point; the deviation of the regulated variable from the set point is called an *error signal*.

Some physiologists prefer the concept of a *settling point* to a set point. A settling point requires neither comparison to a fixed reference nor a physiological embodiment of the error signal. The settling point is simply the value of the regulated variable at which the input and output subsystems are balanced. For example, in the system in Figure 49–1A the settling point is the water level at which inflow equals outflow.

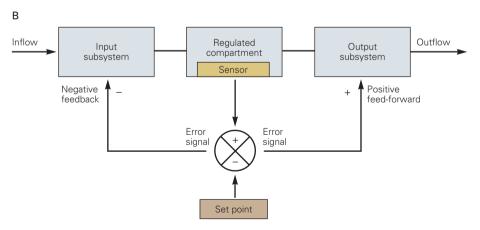

Figure 49–1B Control diagram of the simple regulated system. (Adapted, with permission, from Cabanac and Russek 2000.)

Drinking Occurs Both in Response to and in Anticipation of Dehydration

Severe dehydration generates an overwhelmingly powerful motivational state that focuses thought and action on procuring and consuming water while damping other needs and desires. A dehydrated animal will go to great extremes to find relief from the insistent discomfort of thirst. The behaviors associated with this tightly focused state are classified as *primary drinking* and can be construed as responses to an error signal (Figure 49–1B).

The control system underlying primary drinking enables the animal to respond to a physiological imbalance that would become life threatening if left uncorrected. But additional control over drinking is needed. If water were sought only when the animal was dehydrated, the animal could find itself in an inhospitable environment in which it would have to procure water while in a weakened and deteriorating state. Instead, behavior is programmed so as to avoid severe dehydration. When conditions allow, water is consumed in excess, even in the absence of an error signal, and the kidneys eliminate the surplus. Such *secondary drinking* often coincides with feeding.

In contrast to the simple system in Figure 49–1, physiological systems often comprise several compartmentalized subsystems that are separately regulated. A variety of sensors monitor these separate compartments, and different subsets of effectors are deployed to keep conditions constant within them. Fluid balance provides a case in point. Body water is partitioned between intracellular and extracellular compartments.

Body Fluids in the Intracellular and Extracellular Compartments Are Regulated Differentially

Intracellular and extracellular fluids must be separately regulated because of their different compositions. The principal extracellular cation is Na^+ , whereas the principal intracellular cation is K^+ . Fluctuation in the level of Na^+ is generally more pronounced than that of K^+ . The fluctuations of these cations establish osmolality gradients that move water between the two compartments.

Loss of sodium and water from the extracellular compartment usually occurs with events that lead to decreased vascular volume (hypovolemia), such as hemorrhage or diarrhea. To offset the deficit, both water and sodium must be consumed. Thus primary drinking and sodium intake play essential roles in regulating vascular volume. These behaviors complement the physiological and endocrine mechanisms

that maintain blood pressure while conserving water and sodium.

The Intravascular Compartment Is Monitored by Parallel Endocrine and Neural Sensors

Sensors for hypovolemia include detectors of arterial blood flow to the kidney that send information to the brain through two pathways: an endocrine signaling mechanism and a neural route. The neural pathway originates in vascular stretch receptors on the low-pressure side of the circulation, in the heart, great veins, and pulmonary circulation (baroreceptors). Visceral receptors monitoring the extracellular concentration of Na⁺ and arterial blood pressure are also thought to contribute to fluid homeostasis.

The brain circuitry that controls the behavioral, physiological, and endocrine responses to hypovolemia is distributed along the central nervous system and includes both local and long-loop pathways (Figure 49–2). Baroreceptors project primarily to the nucleus of the solitary tract. A decrease in stimulation of these receptors activates sympathetic output neurons in the caudal brain stem that maintain both blood pressure and cardiac output by increasing heart rate and triggering peripheral vasoconstriction.

Through connections between the caudal brain stem and the hypothalamus, decreased baroreceptor input also drives release of the peptide vasopressin from the posterior pituitary. Vasopressin increases blood pressure and increases reabsorption of water in the kidney (thus its alternate name, *antidiuretic hormone*). Because the kidneys filter an enormous volume of fluid each day—approximately 60 times the plasma volume—adjustment of urinary output has a large and rapid impact on the volume of fluid in the vascular system. This is an example of feed-forward control (Figure 49–1B).

Whereas a decrease of cardiopulmonary baroreceptor firing may stimulate primary drinking, the high-pressure side of the circulation exerts an opposing influence. The nucleus of the solitary tract receives input from peripheral detectors of arterial blood pressure. As the arterial blood pressure increases (eg, during *hyper*volemia), noradrenergic projections from this nucleus to the median preoptic area, a small midline nucleus in the basal forebrain, reduce drinking. This is an example of negative feedback control (Figure 49–1B).

The endocrine signaling mechanism that monitors arterial blood flow functions in parallel with the neural pathway. The reduction in arterial blood flow to the kidneys during hypovolemia causes the release of the protease renin into the circulation. The substrate

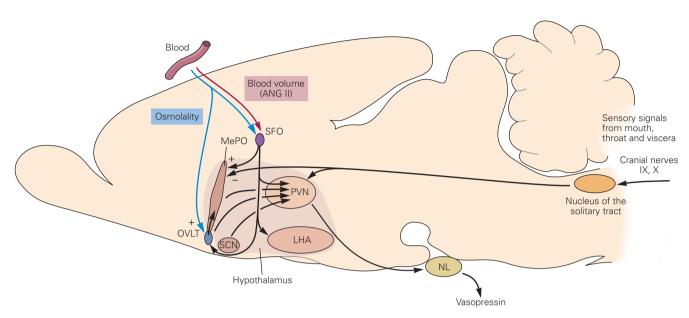

Figure 49-2 Components of the neural circuitry controlling fluid balance. The circuitry is shown in a stylized sagittal section through the rat brain. Information from baroreceptors in the circulatory system and from sensory receptors in the mouth, throat, and viscera is conveyed to the nucleus of the solitary tract and neighboring structures in the caudal brain stem through the glossopharyngeal (IX) and vagal (X) nerves (right side). The hormone angiotensin II (ANG II) provides the brain with an additional signal concerning low blood volume (left side). Circulating angiotensin II is sensed by receptors in the subfornical organ (SFO); SFO neurons project to and release angiotensin II in the median preoptic area (MePO), paraventricular nucleus of the hypothalamus (PVN), vascular organ of the lamina terminalis (OVLT), and adjacent lateral hypothalamic area (LHA). High arterial pressure is detected by baroreceptors that project to the caudal brain stem; when

arterial pressure is too high, drinking is suppressed by an inhibitory input to the median preoptic area from the nucleus of the solitary tract. The osmolality of the blood is sensed by receptors in and near the OVLT that project to the median preoptic area and paraventricular nucleus of the hypothalamus. The latter nucleus is positioned to integrate inputs concerning both blood volume and osmolality and is believed to play a key role in triggering drinking. Neurosecretory cells in this nucleus (and in the supraoptic nucleus) trigger release of vasopressin from the neural lobe (NL) of the pituitary, thus decreasing urinary output. Input to the paraventricular nucleus from the suprachiasmatic nucleus (SCN) brings the fluid-regulatory system under the influence of the internal day/night clock (see Chapter 51). (Adapted, with permission, from Swanson 2000.)

for this protease is the circulating prohormone angiotensinogen, which is cleaved by renin to produce a decapeptide, angiotensin I. In turn, the angiotensin-converting enzyme transforms angiotensin I into angiotensin II, its active octapeptide derivative. The potent vasoconstricting effect of angiotensin II helps maintain blood pressure in the face of decreased vascular volume. Angiotensin II also stimulates aldosterone release from the adrenal cortex. Aldosterone increases reabsorption of Na⁺ in the kidney while favoring K⁺ excretion; these complementary effects shift fluid from the capacious intracellular compartment to the depleted intravascular compartment.

Peptide hormones, such as angiotensin II, do not cross the blood-brain barrier freely. However, the brain is able to monitor the circulation directly through specialized, densely vascularized structures, the

circumventricular organs, which lack a normal bloodbrain barrier and thus provide circulating peptides access to receptors on central neurons. In two of these circumventricular organs, the subfornical organ and vascular organ of the lamina terminalis, angiotensin II acts as a powerful stimulus of drinking and vasopressin release.

Neurons in the subfornical organ project to the median preoptic area and the paraventricular nucleus of the hypothalamus where they release angiotensin II. Injection of angiotensin II into these two nuclei elicits vigorous drinking, whereas cutting the input from the subfornical organ blocks the drinking response to circulating angiotensin II. Thus angiotensin II acts first as a hormone (in the subfornical organ) and then as a neurotransmitter (in the median preoptic area and paraventricular nucleus of the hypothalamus).

The Intracellular Compartment Is Monitored by Osmoreceptors

An increase in extracellular osmolality draws water out of cells, causing the cells to shrink. Changes in cell volume are monitored by specialized neurons called *osmoreceptors*, which translate cell shrinkage or swelling into changes in membrane potential.

A population of central osmoreceptive sensory neurons in the vascular organ of the lamina terminalis projects to neuroendocrine cells in the paraventricular and supraoptic nuclei of the hypothalamus to drive vasopressin release, thus decreasing urinary output (Figure 49–2). Additional projections from these primary sensory neurons to the median preoptic area carry signals that drive drinking in response to cellular dehydration. These latter signals are relayed to the paraventricular nucleus of the hypothalamus, where they converge with inputs from the system that regulates the intravascular compartment.

Motivational Systems Anticipate the Appearance and Disappearance of Error Signals

Changes in intake or expenditure are not immediately registered in physiological systems. For example, water that has been swallowed by an animal undergoing cellular dehydration must be absorbed from the gut and distributed before osmoreceptors of the brain can detect a return toward homeostasis. If consumption continued until the error signal disappeared, the system would overshoot its target. Wastefulness and instability are avoided by terminating drinking well before plasma osmolality is restored.

Thus the regulatory system acts as if it anticipates the cellular rehydration that will eventually follow fluid ingestion, perhaps by using information supplied by peripheral osmoreceptors or visceral Na⁺ receptors. Such anticipatory control is a common feature of motivational systems. For example, migratory birds and whales gain prodigious amounts of weight prior to setting off on their journeys. Unlike the simple regulatory system shown in Box 49–1, the input and output subsystems of motivational systems can be adjusted in anticipation of the appearance and disappearance of error signals.

Energy Stores Are Precisely Regulated

Dieters need little convincing that long-term energy stores are regulated, for they have learned how difficult it is to maintain hard-won weight losses. If we are plump when we are young, we usually remain so. That is, our adiposity relative to the norm for our age tends to remain stable throughout our lives. Recent research on the neural, endocrine, and autonomic mechanisms controlling food intake and energy expenditure is beginning to reveal how energy stores are regulated so precisely.

Leptin and Insulin Contribute to Long-Term Energy Balance

Fat constitutes the long-term energy depot of the body and the brain monitors its state. Elegant experiments in mice first showed that a humoral signal is involved. The circulatory systems of pairs of mice were joined surgically (parabiosis). A normal mouse was paired with a mutant one carrying a recessive homozygous mutation of a gene called *obesity* (*ob*), which produces morbid obesity and hypothermia. This surgical linkage normalized the body weight and temperature of the mutant mouse. The *ob/ob* mouse lacks a circulating signal from energy stores that produces feedback control over food intake and feed-forward control over energy expenditure; the normal partner supplies this signal, correcting the deficits.

Mice with homozygous mutation of the *diabetes* (*db*) gene also are obese. Linking the circulatory system of these mice to that of a normal or *ob/ob* mouse not only failed to correct the diabetes and hypoglycemia, it also caused emaciation and death of the normal or *ob/ob* partner. In contrast to the *ob/ob* mouse, the *db/db* mouse produces the circulating signal but lacks a functional receptor. The signal is elevated in the obese *db/db* mouse, thus decreasing the food intake and increasing the energy expenditures of its unfortunate surgically joined partner.

Some 25 years after the first parabiosis studies, the circulating signal, the mutated receptor, and their genes were identified. The circulating signal was identified by Jeffrey Friedman and his colleagues as a peptide hormone called leptin. It is produced principally by white adipocytes (fat-storing cells) in amounts positively correlated with the level of stored fat. Leptin is transported across the blood–brain barrier and acts in the brain and in the periphery at receptors that are members of the cytokine-receptor superfamily.

In normal-weight individuals leptin reduces food intake while increasing energy expenditure, lipolysis, and thermogenesis. Most obese humans have very high levels of leptin, suggesting that they have become insensitive to this key hormone. The rare humans who lack leptin because of mutation of the *ob* gene are morbidly obese and hypothermic; the body weight and

temperature of such individuals can be normalized by exogenous administration of leptin.

Levels of the pancreatic hormone insulin are also positively correlated with fat mass. Like leptin, insulin reduces food intake and increases thermogenesis. During fasting leptin and insulin levels decrease before the fat stores fall, and thus fat stores are rapidly replenished once eating is resumed.

Circulating leptin and insulin bind to receptors on two populations of neurons in the arcuate nucleus of the medial hypothalamus. These two populations have opposite responses to leptin and insulin and opposite influences on energy balance.

One population of arcuate neurons secretes two anabolic signaling molecules (signals that promote energy storage): neuropeptide Y and agouti-related peptide. The second population secretes two catabolic signaling molecules (signals that promote use of energy stores): α -melanocyte–stimulating hormone and cocaine-and amphetamine-related transcript (Figure 49–3B).

The antagonism between anabolic and catabolic signals from the arcuate nucleus is illustrated by the action of agouti-related peptide. This molecule is an endogenous antagonist of the melanocortin receptors MC3 and MC4. The endogenous agonist at these receptors is the α-melanocyte-stimulating hormone released from arcuate neurons when the organism is in a catabolic state. Agouti-related peptide blocks the ability of the hormone to reduce food intake, increase energy expenditure, and decrease fat storage. Injection of neuropeptide Y into the hypothalamus triggers feeding and promotes lipogenesis while decreasing energy expenditure. Thus release of either peptide produces anabolic feedback and feed-forward effects that promote weight gain while suppressing signaling in the antagonistic catabolic pathway.

Projections from the arcuate nucleus to the paraventricular and lateral regions of the hypothalamus relay signals carried by circulating leptin and insulin (Figure 49–3C). Neurons in these areas have long been implicated in energy balance. For example, bilateral lesions of the paraventricular nucleus increase food intake and body weight, whereas lesions in the lateral hypothalamic area produce opposite effects. Neuropeptides that decrease food intake or increase energy expenditure are released by different subgroups of neurons in the paraventricular nucleus. Neuropeptides that increase food intake are found in separate subgroups of neurons in the lateral and perifornical regions of the hypothalamus.

As with fluid balance, the neural circuitry responsible for energy balance is broadly distributed. This circuitry includes important components in the dorsal

vagal complex of the caudal brain stem in addition to the hypothalamic cell groups described above.

Long-Term and Short-Term Signals Interact to Control Feeding

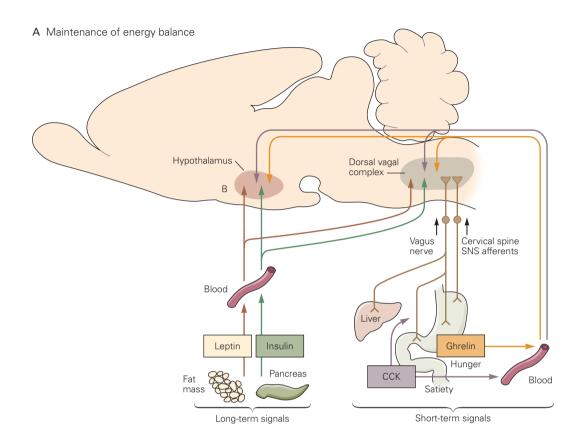

The gastrointestinal tract plays a role in short-term control of ingestive behavior. Two of the gastrointestinal hormones that inform the brain about the state of the gut are cholecystokinin and ghrelin (Figure 49–3A). Cholecystokinin is secreted from the gut during meals. It promotes the termination of the meal by slowing gastric emptying and by stimulating vagal inputs to the lower brain stem circuitry involved in the patterning of meals.

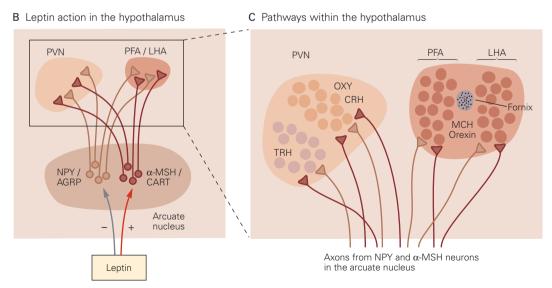

Ghrelin is implicated in the initiation rather than the termination of meals. In contrast to cholecystokinin, release of ghrelin from the stomach peaks prior to a meal, when the stomach is still empty. Ghrelin receptors are found in numerous brain sites; eating has been elicited by direct administration of ghrelin into the arcuate and paraventricular hypothalamic nuclei and the dorsal vagal complex.

To alter food intake, signals such as leptin and insulin, which reflect the state of long-term energy stores, must interact with the short-term signals that determine the composition and patterning of meals. These interactions occur at many levels. For example, leptin promotes the release of cholecystokinin from the duodenum; leptin and ghrelin exert opposing influences on arcuate neurons containing neuropeptide Y and agouti-related peptide. Leptin, insulin, and ghrelin all interact with the 5'-adenosine monophosphateactivated protein kinase (AMPK), a molecular sensor of short-term energy status. To fuel vital physiological processes, cells must maintain a high ratio of adenosine triphosphate (ATP) to 5'-adenosine monophosphate (AMP); AMPK is activated when this ratio falls below a critical threshold. Activation of AMPK stimulates catabolism while suppressing anabolism, thus restoring the ATP/AMP ratio. In hypothalamic neurons implicated in energy balance, leptin, insulin, and high glucose levels all inhibit AMPK activity whereas fasting and ghrelin activate it.

Motivational States Influence Goal-Directed Behavior

So far we have reviewed physiological, neuroendocrine, and neuroanatomical components of the control systems for fluid and energy homeostasis. We now

turn to another feature of homeostatic control systems: the motivational states governing the behaviors that provide the needed inputs, such as food and water.

A cheetah that has taken refuge from the mid-day sun in the shade of a tree greets the sight of a distant antelope with apparent indifference. In contrast, the sighting of an antelope toward the end of the afternoon provokes immediate orientation and stalking. The stimulus is the same, but the behavioral responses are very different. What has changed during the interval, separating the two sightings, is the motivational state of the animal.

Both Internal and External Stimuli Contribute to Motivational States

Motivational states influence attentiveness, goal selection, investment of effort in the pursuit of goals, and responsiveness to stimuli. The psychologist Dalbir Bindra proposed that motivational states arise from the interaction of internal and external inputs.

Internal inputs include physiological error signals and the circadian clock. For example, the frequency and duration of foraging varies with the time of day, the time since the cheetah has last eaten, and whether or not she is lactating. External inputs include *incentive stimuli* arising from the goal of the motivational state. For example, when a dehydrated cheetah comes across a water hole during a search for antelopes, the sight of the water may serve as an incentive stimulus, tipping the balance between hunger and thirst and driving the animal to interrupt its quest for food to drink.

Figure 49–3 (Opposite) Neural and endocrine mechanisms of energy balance.

A. Short- and long-term maintenance of energy balance. *Short-term signals*: During meals cholecystokinin (CCK) from the intestinal tract stimulates sensory fibers of the vagus nerve, thus promoting satiety; CCK is also secreted into the bloodstream. The vagal sensory fibers, along with sympathetic fibers from the gut and orosensory information, converge in the dorsal vagal complex, a set of structures in the caudal brain stem that includes the nucleus of the solitary tract, area postrema, and dorsal motor nucleus of the vagus nerve. Prior to mealtime, release of ghrelin from the stomach peaks, providing a blood-borne signal to neurons in the brain. Whereas CCK promotes satiety, ghrelin promotes eating.

Long-term signals: Leptin and insulin are among the humoral signals that inform the brain about the status of the fat stores. Leptin is produced in fat-storing cells, whereas insulin is produced in the pancreas. Both hormones are sensed by receptors in the arcuate nucleus of the hypothalamus as well as by receptors in the dorsal vagal complex. Leptin and insulin reduce food intake and increase energy expenditure.

There is positive feedback between incentive stimuli and motivational states; the more the animal interacts with the stimulus, the stronger the motivational state that promotes further contact. This positive feedback relationship helps ensure that complex behavioral sequences are completed. For example, the cheetah must stalk, chase, run down, and kill the antelope, and then drag the carcass to a refuge before beginning to feed.

Motivational States Serve Both Regulatory and Nonregulatory Needs

Feeding, drinking, and thermoregulatory behaviors and their underlying motivational states typically arise in response to or in anticipation of a physiological imbalance. In contrast, some motivational states such as sexual arousal serve biological imperatives other than homeostasis. Functionally, these non-regulatory states resemble those arising from physiological error signals. For example, some behaviors influenced by nonregulatory motivational states may be compensatory responses to deprivation, such as when a mammal that has been confined shows heightened motivation to explore once released from captivity.

Brain Reward Circuitry May Provide a Common Logic for Goal Selection

Goal-directed behaviors entail risks, costs, and benefits. Straying from the herd may offer an antelope better opportunities for foraging but at the risk of becoming an easier target for a lurking cheetah. Attacking the

B. Leptin has opposing influences on two populations of arcuate neurons. It inhibits cells that release neuropeptide Y (NPY) and agouti-related peptide (AGRP) but stimulates cells that release $\alpha\text{-melanocyte-stimulating hormone }(\alpha\text{-MSH})$ and cocaine- and amphetamine-regulated transcript (CART). Activation of arcuate neurons that release NPY and AGRP increases food intake and fat storage while decreasing energy expenditure. Activation of arcuate neurons that release $\alpha\text{-MSH}$ and CART decreases food intake and fat storage while increasing energy expenditure.

C. The arcuate neurons shown in part B project to multiple regions of the hypothalamus. The paraventricular nucleus (PVN) is a convergence zone for many signals involved in energy (and fluid) balance. Neurons in this nucleus synthesize several peptides that decrease food intake, including corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), and oxytocin (OXY). The perifornical area (PFA) and lateral hypothalamic area (LHA) contain neurons that synthesize orexins and melanin concentrating hormone (MCH), peptides that stimulate food intake. (Adapted, with permission, from Schwartz et al. 2000.)

venturesome antelope offers the cheetah the promise of a meal with the risk that energetic and hydromineral resources will be depleted if the antelope gets away. Thus the neural mechanisms responsible for goal selection must weigh anticipated risks, costs, and benefits of behaviors that are likely to attain a specific goal.

Many studies of these neural mechanisms have used electrical brain stimulation as a goal. Rats and other vertebrates ranging from goldfish to humans will work for electrical stimulation of certain brain regions. The avidity and persistence of this self-stimulation is remarkable. For example, rats will cross electrified grids, run uphill while leaping over hurdles, or press a lever for hours on end in order to trigger the electrical stimulation. The phenomenon that leads the animal to work for the stimulation is called *brain stimulation reward*.

Rewards are objects, stimuli, or activities that have positive value. Rewards can incite an animal to switch from one behavior to another or to resist interruption of ongoing action. For example, a rat that encounters a seed while scouting the environment may cease exploring to eat the food or carry it to a safe place; while nibbling the seed the rat will resist the efforts of another rat to steal the food from its paws. If seeds are made available only at a particular location and time, the rat will go to that location as the expected moment of reward delivery approaches. Much contemporary work in the neurosciences is directed at unraveling the neural mechanisms that mediate reward, how they shape behavior to meet physiological needs and environmental challenges and opportunities, and how they go awry in the case of behavioral pathologies such as drug addiction.

Although electrical stimulation is an artificial goal, it can mimic some of the rewarding properties of natural goal objects. For example, rewarding stimulation of the medial forebrain bundle can compete with, summate with, or substitute for hedonic stimuli such as sucrose solutions. The effectiveness of the reward produced by stimulating certain lateral hypothalamic sites is increased by weight loss and decreased by leptin, suggesting that the neural circuitry responsible for the rewarding effect plays a role in energy balance.

The circuitry that mediates brain stimulation reward is broadly distributed. Rewarding effects can be produced by electrical stimulation of sites at all levels of the brain, from the olfactory bulb to the nucleus of the solitary tract. Particularly effective sites lie along the course of the medial forebrain bundle and along longitudinally oriented fiber bundles coursing near the midline of the brain stem. Stimulation of both these pathways transsynaptically activates dopaminergic neurons in the ventral tegmental area of the midbrain; these neurons project to the nucleus accumbens (the

major component of the ventral striatum), the ventromedial portion of the head of the caudate nucleus (in the dorsal striatum), the basal forebrain, and regions of the prefrontal cortex (Figure 49–4).

The midbrain dopaminergic neurons are activated by incentive stimuli and play a crucial role in brain stimulation reward. Pursuit of this reward is strengthened by increases in dopaminergic synaptic transmission and weakened by decreases. The dopaminergic neurons receive excitatory signals from cholinergic cells in the laterodorsal tegmental and pedunculopontine nuclei of the hindbrain. Stimulation of the medial forebrain bundle and caudal brain stem activates these cholinergic neurons. In turn, blockade of the cholinergic input to the midbrain dopaminergic neurons reduces the rewarding effects of the electrical stimulation.

Starving rats provided with brief daily access to food will forego eating to press a lever for brain stimulation. Such heedless pursuit of an artificial goal to the detriment of a biological need is one of many parallels between self-stimulation and drug abuse. More direct evidence comes from the fact that the animal will work even harder to self-stimulate when given a drug such as cocaine, amphetamine, heroin, and nicotine. As these results suggest, the midbrain dopaminergic neurons involved in the rewarding effect of brain stimulation also play a critical role in the rewarding effects of drugs.

Drug Abuse and Addiction Are Goal-Directed Behaviors

Before humans began farming, our species foraged for safe and nutritious plants. Among the many plants that humans sampled, a small number produced changes in perception, mood, cognition, or arousal. Of these, a smaller subset—opium poppies, coca, tobacco, hemp, and products of fermented plant matter—contained substances that proved strongly rewarding, even though they lacked any nutritional value. Humans learned to purify these substances and later to synthesize related compounds for use as medicines.

For example, morphine, purified from the opium poppy, was chemically modified in attempts to produce compounds with greater specificity for analgesia. Among these was diacetylmorphine, or heroin, which was mistakenly marketed as a nonaddictive treatment for pain and cough. Other drugs, such as the amphetamines and sedative-hypnotics, are wholly synthetic compounds developed for a variety of medical indications.

Addictive drugs include some with approved medical uses (eg, morphine, amphetamines, and benzodiazepines), some that are legal but lacking in medical

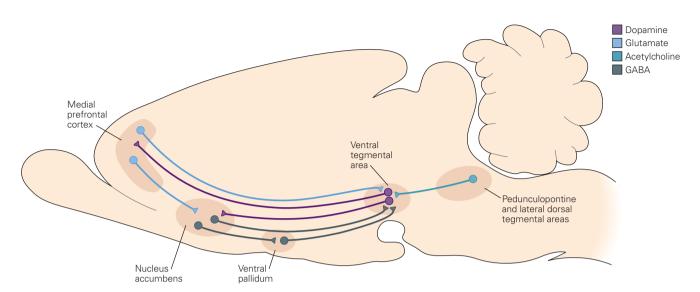

Figure 49–4 Neural pathways and structures implicated in reward. The dopaminergic pathways from the ventral tegmental area to the nucleus accumbens, medial prefrontal cortex, and other forebrain structures are a central component of reward circuitry. The neurons in the ventral tegmental area are

regulated by cholinergic neurons in the brain stem, by inhibitory GABA-ergic (γ-aminobutyric acid) neurons in the nucleus accumbens and ventral pallidum, and by excitatory glutamatergic neurons in the prefrontal cortex.

usefulness (eg, alcohol and tobacco), and some that are illegal in many countries (eg, marijuana). The term *drug abuse* refers to the use of drugs outside of medical supervision and in a manner that is potentially harmful or illegal. The addictive drugs listed in Table 49–1 produce reward; thus, individuals willingly use them and tend to take them repetitively. Herein lies the central danger of these drugs. When used repetitively they initiate molecular changes in the brain that promote continued drug-taking, behavior that becomes increasingly difficult to control. Individuals who regularly use these drugs impair their health and their ability to function.

In people who are vulnerable as a result of genetic and nongenetic risk factors, drug use may progress to *addiction*, which is defined as compulsive drug use despite significantly negative consequences. The addicted person loses control over drug use—obtaining and using drugs come to dominate all other life goals. Addiction tends to persist despite attempts to limit drug use and despite serious negative consequences for the user, his family, and society.

Perhaps the most challenging and frustrating aspect of addiction is its persistence. Not only is it difficult to interrupt active drug use, but even when a person has successfully stopped using drugs the risk of relapse remains high for many years and in some cases for a lifetime. Even after long periods of abstinence, exposure to reminders (cues) of drug use, such as drug

paraphernalia or people or places associated with prior drug use, may trigger intense drug urges and relapse into use. Cue-initiated relapses may occur even in individuals who have strongly resolved never to use drugs again, illustrating that addiction impairs the voluntary control of behavior.

In the laboratory, drug-associated cues elicit drug urges that correlate with physiologic responses, for example, activation of the sympathetic nervous system. Functional brain imaging has revealed that cueconditioned drug responses activate medial regions of the prefrontal cortex; the amygdala, a structure that is thought to play a role in the consolidation of emotionally charged stimulus-reward associations (see Chapters 48 and 66); and the nucleus accumbens, a component of the brain reward circuitry (Figure 49–5).

Addictive Drugs Recruit the Brain's Reward Circuitry

As discussed above, the dopaminergic projections from the ventral tegmental area to the nucleus accumbens and other forebrain structures (Figure 49–4) are a central component of reward circuitry. The major dopamine receptor types in both the dorsal striatum and nucleus accumbens are the D_1 and D_2 G protein-coupled receptors. The D_1 receptors predominate in the prefrontal cortex. A dopamine transporter located

Table 49-1 Major Classes of Addictive Drugs

Class	Source	Molecular target	Examples
Opiates	Opium poppy	μ opioid receptor (agonist)	Morphine, methadone, oxycodone, heroin
Sedative-hypnotics	Synthetic	GABA _A receptor (agonist)	Barbiturates, benzodiazepines
Psychomotor stimulants	Coca leaf Synthetic	Dopamine transporter (antagonist)	Cocaine Amphetamines
Phencyclidine-like drugs	Synthetic	NMDA-type glutamate receptor (antagonist)	Phencyclidine (PCP, "angel dust")
Cannabinoids	Cannabis	CB1 cannabinoid receptors (agonist)	Marijuana
Nicotine	Tobacco	Nicotinic acetylcholine receptor (agonist)	Tobacco
Ethyl alcohol	Fermentation	${ m GABA_A}$ receptor (agonist), NMDA-type glutamate receptor (antagonist), and multiple other targets	Various beverage products

GABA, γ-aminobutyric acid; NMDA, *N*-methyl-D-aspartate.

Note: Caffeine can produce mild physical dependence but does not result in compulsive use. Some illegal drugs that are abused can be harmful but do not generally produce addiction; these include the hallucinogens lysergic acid diethylamide (LSD), mescaline, psilocybin, and 3,4-methylenedioxymethamphetamine (MDMA), popularly known as ecstasy.

on presynaptic neurons terminates the actions of the synaptically released dopamine by pumping it back into the presynaptic terminal (Figure 49–6).

Both pharmacological studies and analyses of lesions in animals confirm the importance of dopaminergic pathways in brain reward. Behavioral studies of the rewarding properties of drugs, using such paradigms as conditioned place preference or self-administration of drugs (Box 49–2), have found that drugs that block D_1 and D_2 dopamine receptors diminish the incentive properties of natural rewards and drugs. Similar conclusions have been reached in studies using other experimental disruptions of dopaminergic pathways.

Changes in extracellular dopamine levels within the nucleus accumbens and other brain structures can be measured in vivo using a microdialysis catheter. Although this method cannot measure dopamine within individual synapses, it can yield quantitative estimates that are thought to correlate with synaptic release of dopamine. This method demonstrates that all addictive drugs increase extracellular dopamine levels in the nucleus accumbens. Thus psychotropic drugs that do not produce significant dopamine release in the nucleus accumbens are not addictive.

There is one important caveat to what is often called the dopamine hypothesis of reward. Some drugs such as opiates also have receptors in reward pathways that are either parallel with or downstream of dopaminergic synapses. Thus opiates produce reward by both dopamine-dependent and dopamine-independent mechanisms. Mice that are genetically engineered to lack dopamine do not find cocaine to be rewarding but appear to gain significant residual reward from morphine.

Although the ability to increase synaptic dopamine is a shared property of all addictive drugs, they do so by different mechanisms. Psychostimulants, which include cocaine and amphetamines, act on the presynaptic terminals of dopaminergic neurons, and they do so in two different ways. Cocaine binds to and blocks the dopamine transporter on the membrane of presynaptic terminals, causing extracellular dopamine to accumulate to high levels following release. Amphetamines enter the presynaptic terminals of dopaminergic neurons through the dopamine transporter. Once in the cytoplasm they cause reverse transport of dopamine out of storage vesicles through the vesicular transporter and out of the neuron into the synapse through the membrane transporter. Thus the action of cocaine

depends on normal vesicular release of dopamine by neurons of the ventral tegmental area, whereas the action of amphetamine does not.

Cocaine and amphetamines have analogous actions on the norepinephrine and serotonin transporters, causing increases in extracellular levels of those neurotransmitters as well. However, pharmacologic blockade and lesion experiments demonstrate that dopamine, not these other neurotransmitters, plays the key role in the rewarding properties of these drugs.

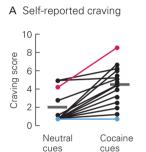

The effects of opiates on reward are more complex than those of the psychostimulants because opiates use both dopamine-dependent and dopamine-independent mechanisms. There are three classes of opioid receptors, μ , δ , and κ , and a structurally related receptor, ORL-1. The morphine-like opiates, including heroin (which is metabolized into morphine), methadone, and oxycodone, bind with highest affinity to μ receptors. The μ receptors are found in several regions of the brain and spinal cord where they serve different functions. In the brain stem and spinal cord they play a critical role in modulating pain information (Chapter 24). In other brain stem regions they play a role in controlling respiration, which is why opiates can cause respiratory arrest in overdose.

Figure 49-5 PET imaging reveals neural correlates of cue-induced cocaine craving.

A. Subjects were shown neutral or cocaine-related cues and asked, "Do you have a craving or urge for cocaine?" The mean score (horizontal bar) is significantly higher for exposure to cocaine-related cues than for exposure to neutral stimuli, even though the magnitude of the response across individuals varies considerably. Two subjects identified by red and blue dots represent high-level and low-level craving, respectively.

B. Changes in self-reported craving are correlated with changes in metabolic rate in the dorsolateral prefrontal cortex and medial temporal lobe during exposure to cocaine-related cues. Metabolic rate is measured as the regional cerebral metabolic rate for glucose (rCMRglc). The ordinate represents the difference between the average of the responses to the question, "Do you have a craving or urge for cocaine?" in separate sessions with neutral and cocaine-related cues. (Each session lasted 30 minutes, and in each session the question was asked three times.) The abscissa represents the difference in metabolic rate between the two sessions (activity with cocaine cues minus activity with neutral cues).

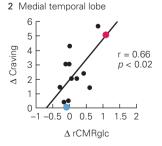

C. When subjects report a craving for cocaine metabolic activity increases in the dorsolateral prefrontal cortex (DLPFC) and in two medial temporal lobe structures, the amygdala (Am) and parahippocampal gyrus (Ph). Pseudocolored PET images of metabolic activity are spatially aligned with high-resolution structural magnetic resonance images. Metabolic rate markedly increased in the amygdala and parahippocampal gyrus in one subject who reported a large increase in craving during presentation of cocaine-related cues (red dot in parts A and B). This effect is not evident in a subject who reported no increase in craving while exposed to the cocainerelated cues (blue dot in parts A and B). Metabolic activity outside the dorsolateral prefrontal cortex and medial temporal lobe is not shown. (Adapted, with permission, from Grant et al. 1996.)

Medial prefrontal cortex Ventral Nucleus tegmental accumbens Neuron in Nucleus nucleus accumbens Dopaminergic neuron Dopamine from ventral transporter tegmental area Glutamate Dopamine receptor Glutamatergic neuron from cortex

Figure 49–6 Dopamine and glutamate interact at synaptic spines in nucleus accumbens neurons. Glutamatergic neurons carrying sensorimotor information from the cerebral cortex and dopaminergic neurons carrying reward-related information from the ventral tegmental area form connections with the same medium spiny neurons in the dorsal striatum and nucleus accumbens. The glutamatergic neurons make excitatory synapses on the heads of dendritic spines and the dopaminergic neurons make en passant connections at the necks of spines.

The μ receptors are also found throughout brain reward circuitry. In the ventral tegmental area they are found on GABA-ergic interneurons that tonically inhibit the dopaminergic neurons that project to the nucleus accumbens and prefrontal cortex. Opiate binding to these μ receptors inhibits the interneurons, resulting in disinhibition of the dopaminergic neurons and dopamine release. Because μ receptors are also expressed by nucleus accumbens neurons, opiates can also exert rewarding effects independent of dopamine inputs.

Microdialysis demonstrates that nicotine, ethyl alcohol, tetrahydrocannabinol, and phencyclidine all cause dopamine to be released in the nucleus accumbens. In addition to their shared effect—increasing synaptic dopamine in the nucleus accumbens—each family of addictive drugs has unique properties based on the receptors with which they interact (Table 49–1). For example, both morphine and cocaine are rewarding and addictive, morphine-like opiates are analgesic and sedating, and cocaine stimulates arousal.

Addictive Drugs Alter the Long-Term Functioning of the Nervous System

In addition to producing short-term reward and other acute pharmacologic effects, addictive drugs can produce long-term alterations in the functioning of the nervous system. Repeated use of addictive drugs can produce tolerance, dependence, withdrawal, and sensitization to differing degrees, as well as addiction. In humans tolerance, dependence, and withdrawal can all contribute to altered behavior. The behavioral consequences of sensitization, a phenomenon well established in animal models, are less clear for human drug users. None of these states is equivalent to addiction, which is defined as compulsive drug use despite significant negative consequences.

Tolerance refers to the diminishing effect of a drug after repeated ingestion of the drug at a constant dose, or alternatively the need to increase the dose to produce a constant effect. For example, the amount of alcohol needed to get drunk increases with regular use. Tolerance results from homeostatic responses of cells to excessive drug stimulation—molecular and cellular adaptations alter normal physiology to counterbalance the effects of the drug. One mechanism of tolerance is

pharmacokinetic, in which induction of hepatic metabolic enzymes increase the rate of metabolic clearance of a drug. Pharmacokinetic adaptation plays almost no role in tolerance for addictive drugs other than alcohol. A second mechanism is *pharmacodynamic*: The action of a drug within the brain that produces habituation.

Dependence is inferred when withdrawal symptoms occur after drug use is curtailed. Whereas tolerance results from homeostatic mechanisms those associated with dependence alter the basal physiological state of cells and circuits. As long as drug use continues, this altered physiology is masked and symptoms do not occur. Cessation of drug use unmasks the abnormal physiological state, resulting in withdrawal symptoms.

When effects grow stronger with repeated drug use they are said to undergo *sensitization*. For example, the locomotor activity produced by amphetamine or cocaine increases with repeated use of the drug. In general the stimulant effects of a drug are more likely to increase (sensitization), whereas depressant effects tend to diminish (tolerance).

The mechanisms by which opiates produce tolerance, dependence, and a withdrawal syndrome have been elucidated in studies of the behavior of neurons in the locus ceruleus, the major noradrenergic nucleus

Box 49–2 Animal Models of Drug Addiction

Animal models have played an important role in understanding how addictive drugs produce reward. Two of the most commonly used in research are conditioned place preference and self-administration.

Conditioned Place Preference

Animals learn to associate a particular environment with passive exposure to drugs; for example, a rodent may spend more time on the side of a box where it was given cocaine than on the side where it received saline. In experiments using this paradigm animals learn to associate a neutral cue, such as the features of one side of a box, with a reward. This paradigm is believed to demonstrate the strong cue-conditioned effects of addictive drugs and to provide an indirect measure of drug reward.

Self-Administration of Drugs

The reinforcing effects of a drug can be demonstrated in experiments in which a specific behavior produces the

drug. For example, an animal may be taught that it will receive an injection of a drug every time it presses a particular lever in its cage. The drug acts as a reinforcer if it increases the occurrence of the behavior (pressing the lever) that leads to acquisition of the drug.

In this paradigm the amount of work an animal does to gain access to a given amount of drug indicates the reinforcing strength of the drug. The strength with which different drugs reinforce behavior in animals correlates well with the tendency of each drug to reinforce drug-seeking behavior in humans. Laboratory animals exposed to cocaine readily learn behaviors necessary to self-administer this drug and some of them will give up necessities, such as food and water, or work excessively, even to the point of death, to gain access to cocaine.

in the brain. Acute administration of opiates to rats or mice slows the basal firing rate of locus ceruleus neurons because μ opioid receptors activate a K^+ channel that reduces the firing rate. Over time, however, the neurons develop tolerance; their firing rate becomes more normal as the μ receptors become partly uncoupled from channel activation.

Chronic opiate administration also produces dependence that sets the stage for withdrawal. Following chronic opiate administration, blockade of μ receptors by the opioid receptor antagonist naloxone produces a dramatic withdrawal syndrome. (This is observed in laboratory rats, which exhibit such withdrawal symptoms as "wet dog" shakes, as well as in opiate-dependent humans given naloxone to reverse respiratory arrest.) One mechanism that contributes to dependence is the strengthening of a Na⁺ conductance in locus ceruleus neurons; this adaptation can act to balance the efflux of $K^{\scriptscriptstyle +}$ produced by μ receptor stimulation. The relative excess of Na⁺ influx following naloxone inhibition of μ receptor-mediated K⁺ efflux renders the neurons hyperexcitable. This results in burst firing that correlates with withdrawal behaviors.

Historically, dependence and physical withdrawal were thought to be cardinal features of addiction. We now know that they are neither necessary nor sufficient. First, some drugs such as cocaine and amphetamines that readily cause compulsive, "out of control" use may produce little or no dependence and do not produce physical withdrawal. More importantly, the risk of relapse into drugs that can produce physical withdrawal, such as opiates and alcohol, can persist for years after drug use has stopped and withdrawal symptoms have resolved.

If dependence and withdrawal were the central mechanisms of addiction, we could successfully treat addicted people by sequestering them until they were well past the period of withdrawal. Unfortunately this is not the case, as stress or drug-related cues can readily cause relapse. Based on the important role of drug-associated cues in drug-seeking and relapse, some clinical investigators have emphasized the need to consider the neural mechanisms of associative learning as central to addiction.

Dopamine May Act As a Learning Signal

An earlier view of the function of dopamine was that it conveyed "hedonic signals" in the brain and that in humans it was directly responsible for subjective pleasure. From this point of view addiction would reflect the habitual choice of short-term pleasure despite a host of long-term life problems. However, the hedonic principle

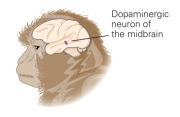

cannot easily explain the persistence of drug use by addicted persons as negative consequences mount.

In fact, the effects of dopamine have proven to be far more complex than was first thought. Dopamine can be released by stressful as well as by rewarding stimuli. Moreover, rodents lacking dopamine—rats in which dopamine is depleted by 6-hydroxydopamine and mice genetically engineered so that they cannot produce dopamine—continue to exhibit hedonic responses to sucrose.

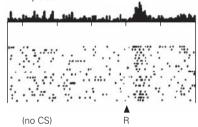

Wolfram Schultz and his colleagues discovered that dopaminergic neurons have a complex and changing pattern of responses to rewards during learning. In one experiment Schultz trained monkeys to expect juice at a fixed interval after a visual or auditory cue. Before the monkeys learned the predictive cues, the appearance of the juice was unexpected and produced a transient increase above basal levels of firing in dopaminergic neurons. As the monkeys learned that certain cues predict the juice, the timing of the firing changed. The neurons no longer fired in response to presentation of the juice—the reward—but earlier, in response to the predictive visual or auditory cue. If a cue was presented but the reward was withheld, firing paused at the time the reward would have been presented. In contrast, if a reward exceeded expectation or was unexpected, because it appeared without a prior cue, firing was enhanced (Figure 49–7).

These observations suggest that dopamine release in the forebrain serves not as a pleasure signal but as a prediction-error signal. A burst of dopamine would signify a reward or reward-related stimulus that had not been predicted; pauses would signify that the predicted reward is less than expected or absent. If a reward is just as expected based on environmental cues, dopaminergic neurons would maintain their tonic (baseline) firing rates. Alterations in dopamine release are thought to modify future responses to stimuli to maximize the likelihood of obtaining rewards and to minimize fruitless pursuits. For natural rewards, like the sweet juice consumed by the monkeys in Schultz's experiments, once the environmental cues for a reward are learned, dopaminergic neuron firing returns toward baseline levels. Schultz has interpreted this to mean that as long as nothing changes in the environment, there is nothing more to learn and therefore no need to alter behavioral responses.

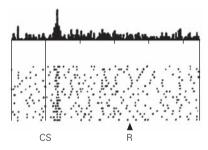

Addictive drugs differ from natural rewards in that they cause dopamine release in the reward circuitry no matter how often they are consumed. Dopamine is released even when these drugs do not produce subjective pleasure. To the brain, consumption of addictive drugs would thus always signal "better than expected" and in this way would continue to influence behavior to maximize drug-seeking and drug-taking.

Unexpected reward

Predicted reward

Reward predicted but does not occur

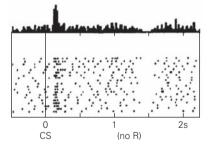

Figure 49-7 Dopaminergic neurons report an error in reward prediction. Graphs show firing rates recorded from midbrain dopaminergic neurons in awake, active monkeys. Top: A drop of sweet liquid is delivered without warning to a monkey. The unexpected reward (R) elicits a response in the neurons. The reward can thus be construed as a positive error in reward prediction. Middle: The monkey has been trained that a conditioned stimulus (CS) predicts a reward. In this record the reward occurs according to the prediction and does not elicit a response in the neurons because there is no error in the prediction of reward. The neurons are activated by the first appearance of a predicting stimulus but not by the reward. Bottom: A conditioned stimulus predicts a reward that fails to occur. The dopaminergic neurons show a decrease in firing at the time the reward would have occurred. (Reproduced, with permission, from Schultz et al. 1997.)

If this idea is correct, it might explain why drugseeking and consumption become compulsive and why the life of the addicted person becomes focused on drugtaking at the expense of all other pursuits.

These experiments, combined with the importance of cues in promoting drug taking, have suggested that learning and memory might play a central role in addiction. For example, drug-seeking is often initiated by drug-related cues—the people, paraphernalia, bodily sensations, and smells associated with prior drug use. Such cues must, of course, be stored in memory and associated with specific behaviors. Interestingly, dopamine has been implicated in the formation of long-term memories in hippocampal and cerebral cortical circuits (Chapters 66 and 67).

These considerations have led to the idea that when someone uses addictive drugs the release of dopamine strengthens the associative memories that bind drugrelated cues to drug urges and drug-seeking. The brain reward circuitry that normally reinforces the pursuit of goals with positive survival value is usurped by drugrelated goals.

If dopamine-dependent associative memory processes are involved in the pathogenesis of addiction, what cellular and molecular mechanisms might be involved? Long-term change in synaptic function is a fundamental property of neural circuits involved in learning. The best characterized physiologic mechanisms of such long-term changes in the mammalian brain are long-term potentiation and long-term depression (Chapters 66 and 67). These mechanisms are thought to underlie many different types of learning and memory. Indeed, drug use can lead to synaptic changes similar to long-term potentiation and depression in the striatum and nucleus accumbens, as well as in the midbrain dopaminergic neurons themselves.

Activation of the dopaminergic pathways also resembles learning in that these pathways are capable of initiating many changes in gene expression. Relating these changes to learning-related alterations in synaptic connections and circuit function remains an important challenge. For example, dopamine action at the D₁ receptors leads to the activation of the transcription factor cyclic AMP response element binding protein (CREB). CREB has been implicated in diverse memory processes in a variety of species, including the *Drosophila* fly, the marine snail *Aplysia*, and mice (Figure 49–8, and see Chapters 66 and 67). In the dorsal striatum and nucleus accumbens, psychostimulants produce phosphorylation of CREB through activation of the D₁ receptors and the second messenger cyclic AMP. This leads to activation of the cAMPdependent protein kinase, which then phosphorylates CREB, leading to its activation. A large number of

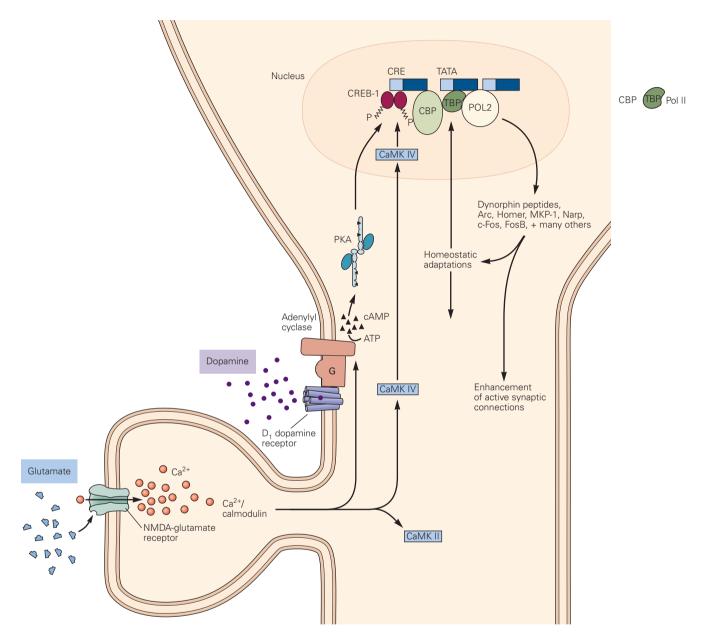

Figure 49–8 Intracellular signaling pathways activated by dopamine and glutamate. NMDA-type glutamate receptors permit Ca²⁺ entry, which binds calmodulin. The Ca²⁺/calmodulin complex activates two Ca²⁺/calmodulin-dependent protein kinases, CaMKII in the cytoplasm and CaMKIV in the cell nucleus. D₁ dopamine receptors activate a stimulatory G protein that in turn activates the adenylyl cyclase to produce cyclic adenosine monophosphate (AMP). The cyclic AMP-dependent protein kinase (protein kinase A or PKA) catalytic subunit can enter the nucleus. In this diagram PKA and CaMKIV phosphorylate and thus activate the cyclic AMP response element

binding protein (CREB). CREB recruits CREB-binding protein (CBP) and thus activates the RNA polymerase II-dependent transcription of many genes, giving rise to proteins that can alter cellular function. Arc and Homer are localized in synaptic regions; Fos and FosB are transcription factors; and dynorphin gives rise to a family of endogenous opioid peptides. These proteins are thought to contribute both to homeostatic responses to excessive dopamine stimulation and to the remodeling of synapses associated with memory formation. (NMDA, N-methyl-D-aspartate; POL 2, RNA polymerase 2; TBP, TATA binding protein.)

CREB-regulated genes are thus induced by dopamine and psychostimulants.

An Overall View

The ability of cells, organs, and organisms to survive and function in the face of changing conditions such as alterations in temperature or nutrient availability depends on mechanisms that maintain a relatively constant internal milieu. Complex brain circuits orchestrate the physiological processes that redistribute and transform internal resources such as water, electrolytes, and energy stores to correct and anticipate deviations from homeostasis. Tightly integrated with these circuits are the neural systems mediating behaviors that procure vital resources from the environment and help to conserve scarce supplies or expend surpluses.

Motivational states adjust the vigor and incidence of these behaviors according to biological needs, both those stemming from regulatory imperatives such as the maintenance of blood volume and those stemming from nonregulatory imperatives such as reproduction. The strength of a motivational state depends not only on internal conditions but also on external incentive stimuli such as food or estrus odors.

Choosing between competing incentives requires that the current and predicted benefit of each incentive be assessed, a task attributed to brain reward circuitry. Activation of this circuitry creates resistance to interruption of ongoing actions and promotes behaviors that anticipate or procure rewards.

The dopaminergic projection from the ventral tegmental area to the nucleus accumbens powerfully influences goal-directed behavior. All addictive drugs increase synaptic dopaminergic transmission in this pathway, an effect that may mimic and ultimately overwhelm the influence of natural stimuli and motivational states. Dopamine facilitates the cellular and molecular mechanisms of learning and memory. In vulnerable individuals drug-associated cues may be transformed into powerful incentive stimuli. Thus reminders of prior drug use may precipitate relapses to drug-seeking despite the disastrous consequences that a return to drug use might bring. Such a state of addiction is not easily abolished, and relapse remains a serious risk even after many years of abstinence.

An Overall View

TATIL QUITE RECENTLY THE FUNCTION and organization of the human cerebral cortex—the structure of the brain concerned with perceptual, motor, and cognitive functions—has eluded both clinicians and neuroscientists. In the past the analysis of brain function relied in large part on observations of the behavioral consequences of brain damage caused by strokes or trauma. These natural experiments provided much of the early evidence that distinct brain regions serve specific functions (see Chapter 1).

Observation of patients with seizures and epilepsy has been equally important in the study of brain function because the behavioral consequences of these disorders vary with the brain regions from which they originate. *Seizures* are temporary disruptions of brain function resulting from abnormal, excessive neuronal activity; *epilepsy* is a chronic condition of repeated seizures. For centuries understanding the neurological origins of seizures was confounded by the dramatic, sometimes bizarre behaviors associated with seizures. Epilepsy was widely associated with possession by evil spirits, while seizures were thought to reflect oracular, prescient, or special creative powers.

The Greeks in the time of Hippocrates (circa 400 BC) were aware that head injuries to one side of the brain could cause seizure activity on the opposite side of the body. In those earlier times the diagnosis of epilepsy was probably much broader than the contemporary definition. Other causes of episodic unconsciousness, such as syncope as well as mass hysteria and psychogenic seizures, were almost certainly classified with epilepsy. Moreover, historical writings typically describe generalized convulsive seizures involving both cerebral hemispheres. Thus it is likely that focal

seizures involving a limited area of the brain were misdiagnosed or never diagnosed at all. Even today it can be difficult for physicians to distinguish between episodic loss of consciousness and the various types of seizures. Nevertheless, as our ability to treat and even cure epilepsy continues to improve, these diagnostic distinctions take on increasing significance.

The modern neurobiological analysis of epilepsy began with John Hughlings Jackson's work in London in the 1860s. Jackson realized that seizures need not involve loss of consciousness but could be associated with localized symptoms such as the jerking of an arm. His observation was the first formal recognition of what we now call *focal* (or *partial*) *seizures*. Jackson also observed patients whose seizures began with focal neurological symptoms and progressed to convulsions with loss of consciousness (the so-called Jacksonian march).

Another early development that presaged modern therapy was the first surgical treatment for epilepsy in 1886 by Victor Horsley. Horsley resected cerebral cortex adjacent to a depressed skull fracture and cured a patient with focal motor seizures. The modern surgical treatment for epilepsy dates to the work of Wilder Penfield and Herbert Jasper in Montreal in the early 1950s. Medical innovations include the first use of phenobarbital as an anticonvulsant in 1912 by Alfred Hauptmann, the development of electroencephalography by Hans Berger in 1929, and the discovery of the anticonvulsant properties of phenytoin (Dilantin) by Houston Merritt and Tracey Putnam in 1937.

As in any chronic disease, the physiological features of seizures are not the only consideration in the care and management of patients with epilepsy. Psychosocial factors are also extremely important. The diagnosis of epilepsy has consequences that can affect all aspects of everyday life, including educational opportunities, driving, and employment. Although many limitations imposed on epileptics are appropriate—most would agree that patients with epilepsy should not be commercial pilots—a diagnosis of epilepsy can have inappropriate, negative effects on educational opportunities and employment. To improve this situation, physicians have a duty to educate themselves and the public.

Classification of Seizures and the Epilepsies Is Important for Pathogenesis and Treatment

Not all seizures are the same. Thus the pathology of seizures must take into account their clinical features. Seizures, and the chronic condition of repetitive seizures (epilepsy), are common. Based on epidemiological studies in the United States, somewhere around 3% of all individuals living to the age of 80 years are diagnosed with epilepsy. The highest incidence occurs in young children and the elderly.

In many respects seizures represent a prototypic neurological disease in that the symptoms include both positive and negative sensory or motor manifestations. Examples of positive signs that can occur during a seizure include the perception of flashing lights or the jerking of an arm. Negative signs such as impairment of consciousness and self-awareness or even transient blindness or paralysis reflect impairment of normal brain function. These examples underscore a general feature of seizures: The signs and symptoms depend on the location and extent of brain regions that are affected. Finally, the manifestations of seizures result in part from the activity in normal tissue with normal cellular and network properties. The latter is particularly important in the spread of a focal or partial seizure beyond its original boundaries. Seizures quite literally hijack the normal functions of the brain.

Seizures Are Temporary Disruptions of Brain Function

Seizures can be classified conceptually into two categories: focal (or partial) and generalized (Table 50–1). Although the details of seizure classification are under continuous discussion, this simple dichotomy has proven extremely useful to clinicians because anticonvulsant medications often target preferentially to

Table 50–1 International League Against Epilepsy (ILAE) Classification of Seizures

one or the other type of seizure. The terms "focal" and "partial" are used interchangeably in this chapter.

Focal seizures originate in a small group of neurons (the seizure focus) and thus the symptoms depend on the location of the focus within the brain. Focal seizures were formerly classified as simple partial when there is no alteration of consciousness, or complex partial when there is an alteration of consciousness. A typical focal seizure might begin with jerking in the right hand and progress to clonic movements (ie, jerks) of the entire right arm. This seizure could also be called a *focal motor seizure*. If a focal seizure progresses further the patient may lose consciousness, fall to the ground, rigidly extend all extremities (tonic phase), then have jerking in all extremities (clonic phase). In this case, the focal seizure has secondarily generalized.

The onset of a focal seizure is often preceded by symptoms called *auras*. Common auras include abnormal sensations such as a sense of fear, a rising feeling in the abdomen, or even a specific odor. The aura is caused by electrical activity originating from the seizure focus and thus represents the earliest manifestations of a focal seizure. The time after a seizure but before the patient returns to his or her normal level of neurological function is called the *postictal period*.

Generalized seizures constitute the second main category. They begin without an aura or focal seizure and involve both hemispheres from the onset. Thus they are sometimes called *primary generalized seizures* to avoid confusion with seizures that begin from a focus and then generalize secondarily. Primary generalized seizures can be further divided into convulsive or nonconvulsive types depending on whether the seizure is associated with tonic or clonic movements.
